Figure 4.7: **CMIP6 carbon uptake in historical and scenario simulations.** (a) Atmosphere to ocean carbon flux (PgC yr^{-1}). (b) Atmosphere to land carbon flux (PgC yr^{-1}). The curves show ensemble averages and the shadings show the 5–95% ranges across the SSP1-2.6 and SSP3-7.0 ensembles. The numbers inside each panel are the number of model simulations. The land uptake is taken as Net Biome Productivity (NBP) and so includes any modelled net land-use change emissions. Results are from concentration-driven simulations. Further details on data sources and processing are available in the chapter data table (Table 4.SM.1).

ACCEPTED VERSION SUBJEC TO FINAL EDITS

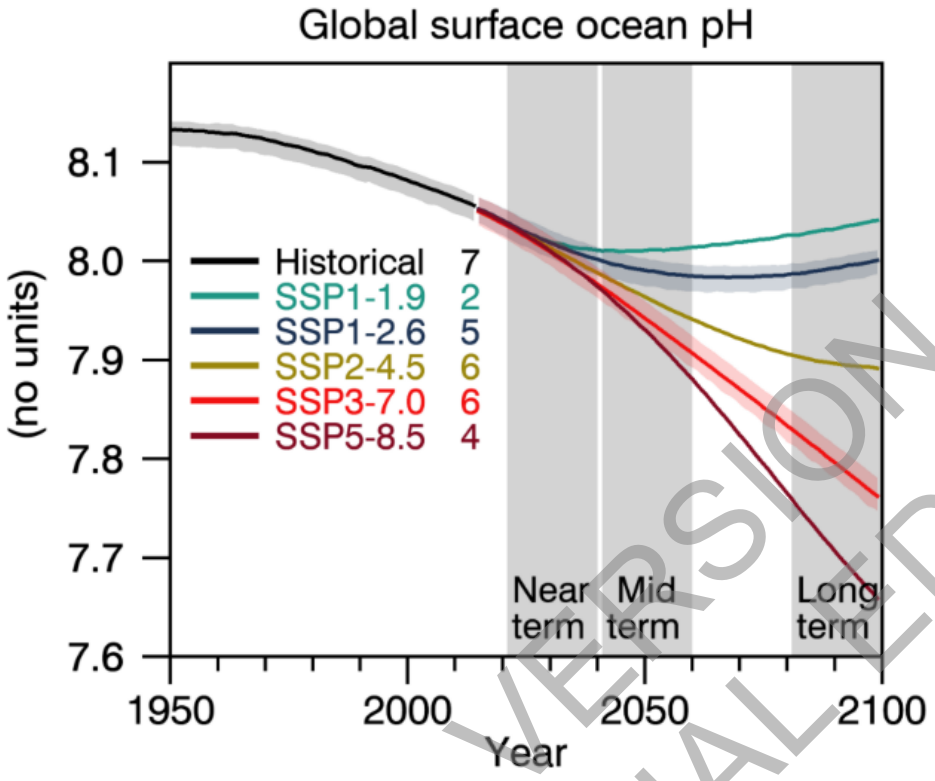

Figure 4.8: **Global average surface ocean pH**. The shadings around the SSP1-2.6 and SSP5-7.0 curves are the 5–95% ranges across those ensembles. The numbers inside each panel are the number of model simulations. Results are from concentration-driven simulations. Further details on data sources and processing are available in the chapter data table (Table 4.SM.1).

ACCEPTED VERSION SUBJEC TO FINAL EDITS

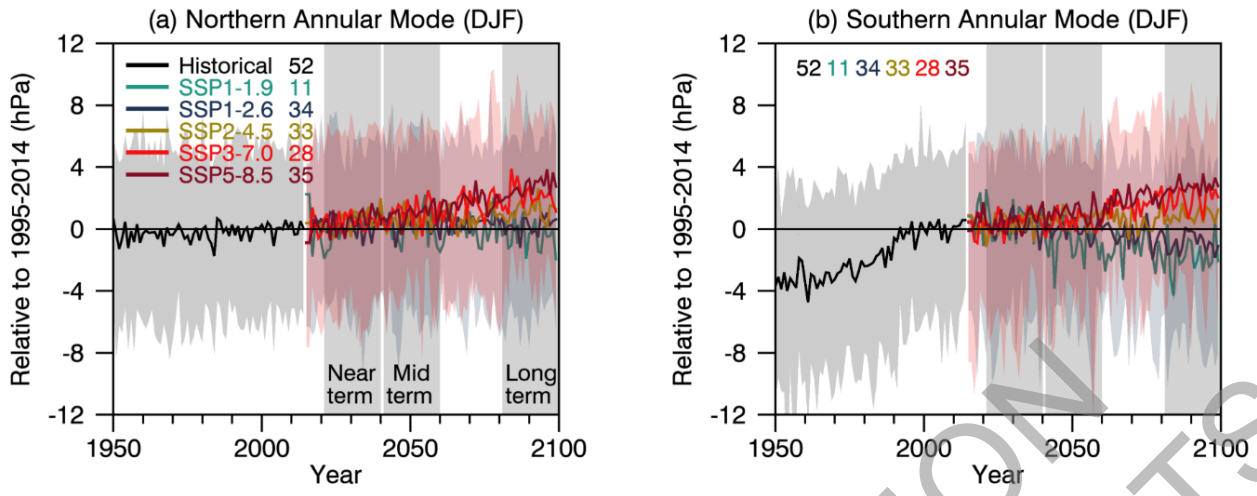

Figure 4.9: **CMIP6 simulations of boreal wintertime (DJF) Annular Mode indices.** (a) NAM and (b) SAM. The NAM is defined as the difference in zonal mean SLP at 35°N and 65°N (Li and Wang, 2003) and the SAM as the difference in zonal mean SLP at 40°S and 65°S (Gong and Wang, 1999). All anomalies are relative to averages from 1995–2014. The curves show multi-model ensemble averages over the CMIP6 r1 simulations. The shadings around the SSP1-2.6 and SSP3-7.0 curves denote the 5–95% ranges of the ensembles. The numbers inside each panel are the number of model simulations. The results are for concentration-driven simulations. Further details on data sources and processing are available in the chapter data table (Table 4.SM.1).

ACCEPTED VERSION SUBJEC TO FINAL EDITS

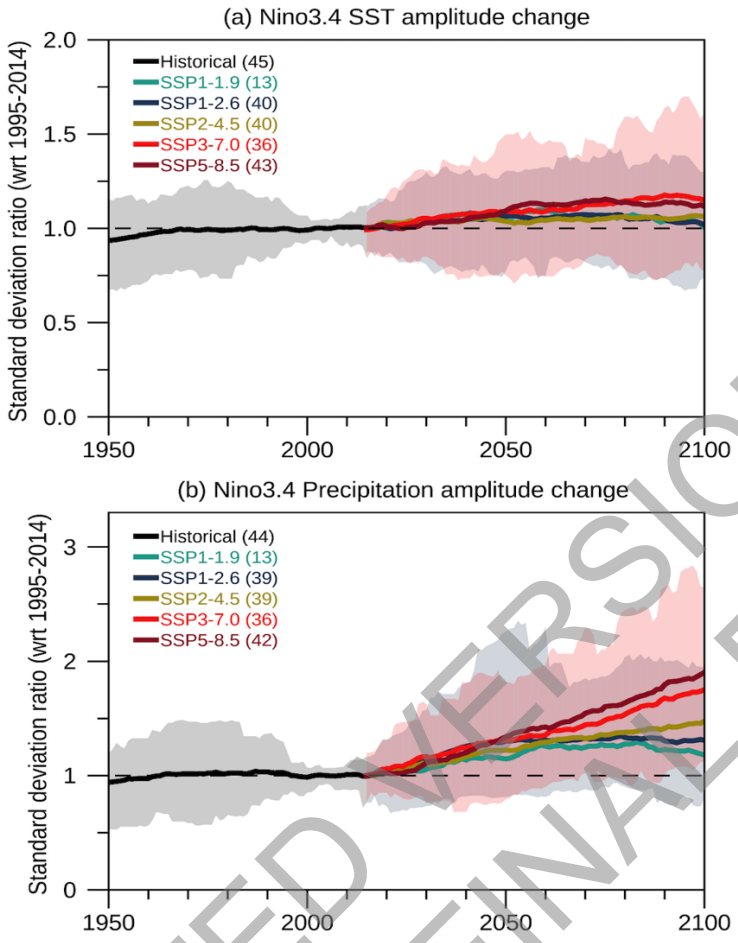

Figure 4.10: Changes in amplitude of ENSO Variability. Variability of (a) SST and (b) precipitation anomalies averaged over Niño3.4 region for 1950–2014 from CMIP6 historical simulations and for 2015–2100 from four SSPs. Thick lines stand for multi-model mean and shading is the 5–95% range across CMIP6 models for historical simulation (grey), SSP1-2.6 (blue) and SSP3-7.0 (pink), respectively. The amplitude of ENSO SST and rainfall variability is defined as the standard deviation of the detrended Niño3.4-area averaged SST and rainfall index, respectively, over 30-year running windows. The standard deviation in every single model is normalized by each model's present-day standard deviation averaged from 1995 to 2014. The number of available models is listed in parentheses. This figure is adopted from (Yun et al., 2021). Further details on data sources and processing are available in the chapter data table (Table 4.SM.1).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

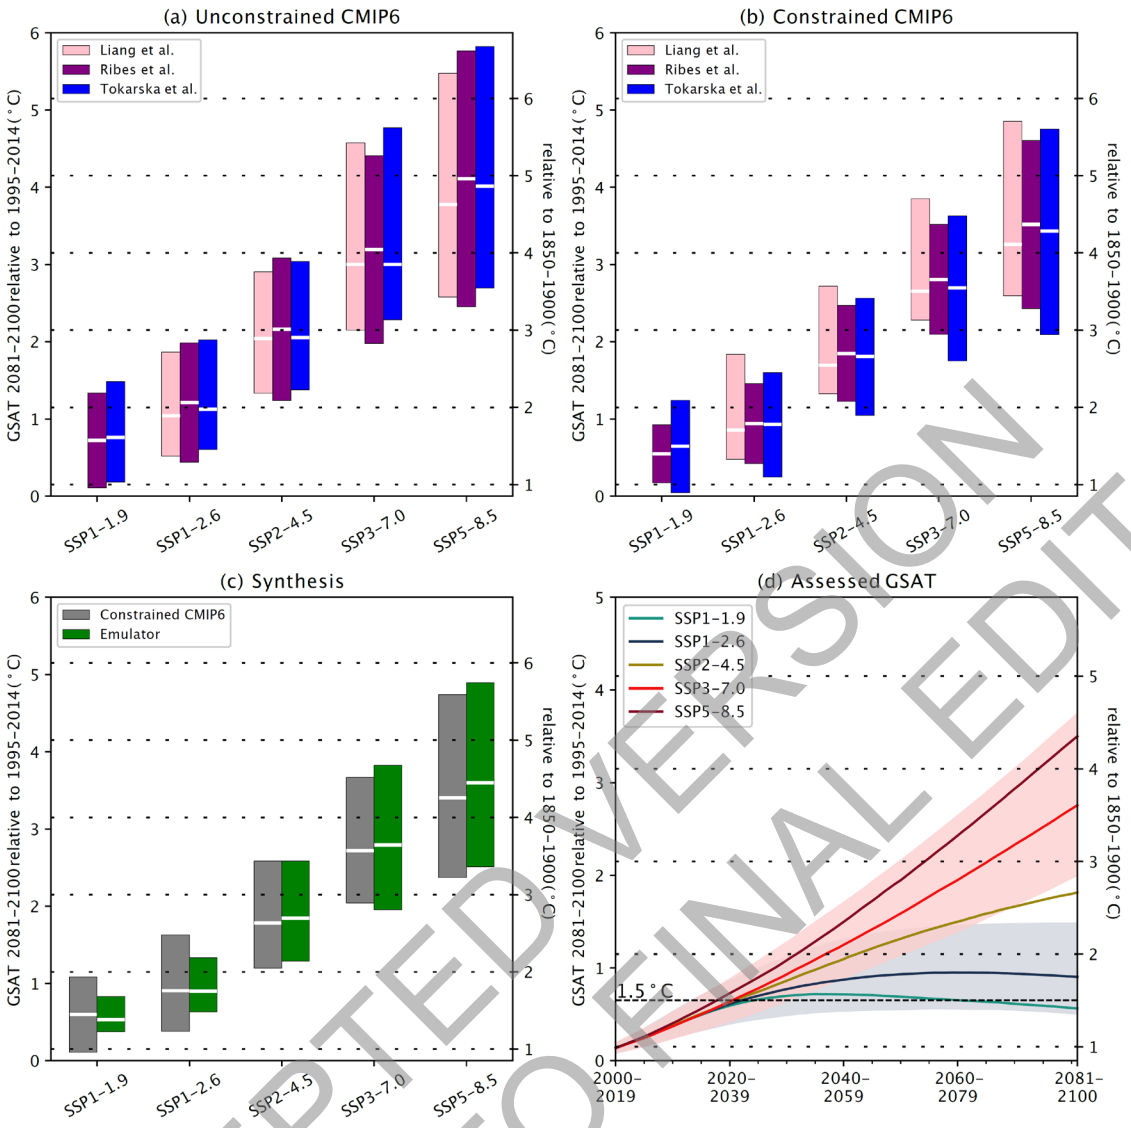

Figure 4.11: Multiple lines of evidence for GSAT changes for the long-term period, 2081–2100, relative to the average over 1995–2014, for all five priority scenarios. The unconstrained CMIP6 5–95% ranges (coloured bars) in (a) differ slightly because different authors used different subsamples of the CMIP6 archive. The constrained CMIP6 5–95% ranges (coloured bars) in (b) are smaller than the unconstrained ranges in (a) and differ because of different samples from the CMIP6 archive and because different observations and methods are used. In (c), the average of the ranges in (b) is formed (grey bars). Green bars in (c) show the emulator ranges, defined such that the best estimate, lower bound of the *very likely range*, and upper bound of the *very likely* range of climate feedback parameter and ocean heat uptake coefficient take the values that map onto the corresponding values of ECS and TCR of Section 7.5 (see BOX 4.1). The time series in (d) are constructed by taking the average of the constrained CMIP6 ranges and the emulator ranges. The y-axes on the right-hand side are shifted upward by 0.85°C, the central estimate of the observed warming for 1995–2014, relative to 1850–1900 (Cross-Chapter Box 2.3, Table 1). Further details on data sources and processing are available in the chapter data table (Table 4.SM.1).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

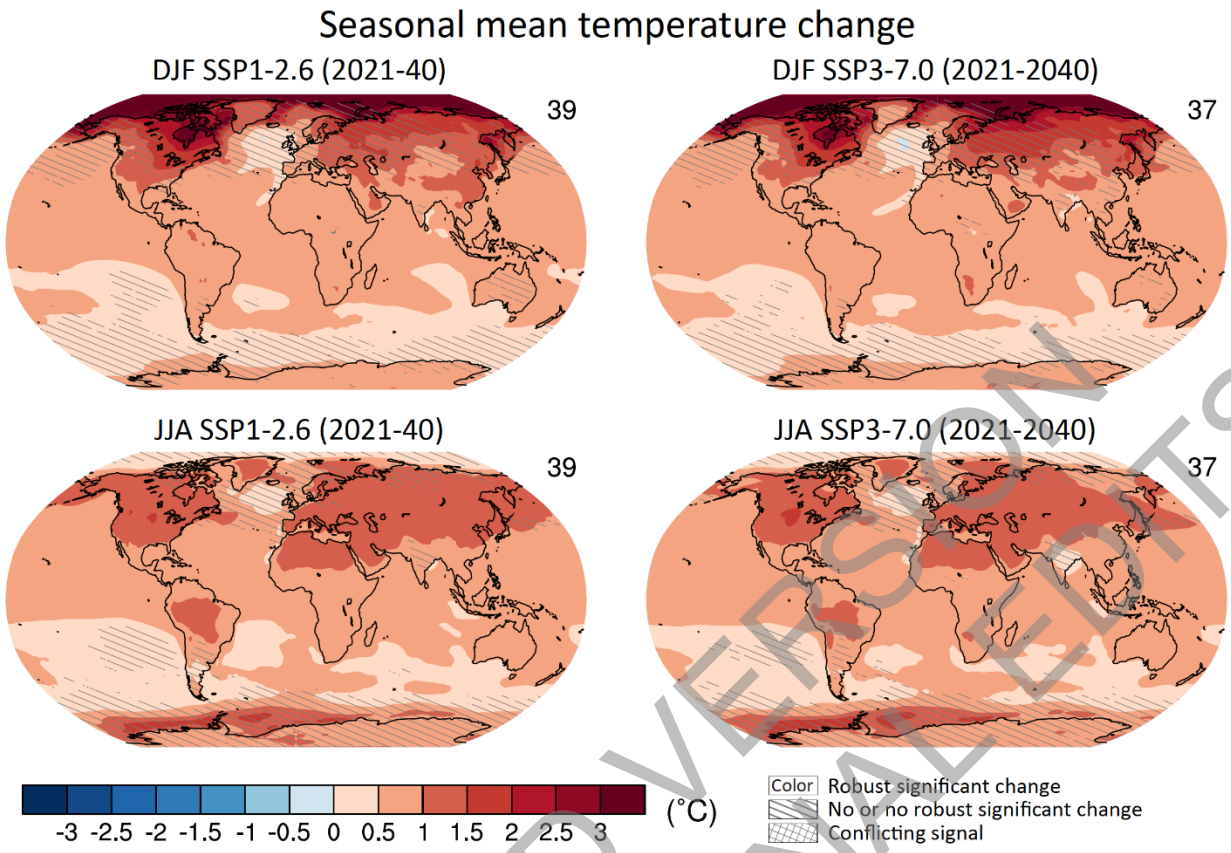

Figure 4.12: Near-term change of seasonal mean surface temperature. Displayed are projected spatial patterns of CMIP6 multi-model mean change (°C) in (top) DJF and (bottom) JJA near-surface air temperature for 2021–2040 from SSP1-2.6 and SSP3-7.0 relative to 1995–2014. The number of models used is indicated in the top right of the maps. No overlay indicates regions where the change is robust and *likely* emerges from internal variability, that is, where at least 66% of the models show a change greater than the internal-variability threshold (see Section 4.2.6) and at least 80% of the models agree on the sign of change. Diagonal lines indicate regions with no change or no robust significant change, where fewer than 66% of the models show change greater than the internal-variability threshold. Crossed lines indicate areas of conflicting signals where at least 66% of the models show change greater than the internal-variability threshold but fewer than 80% of all models agree on the sign of change. Further details on data sources and processing are available in the chapter data table (Table 4.SM.1).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

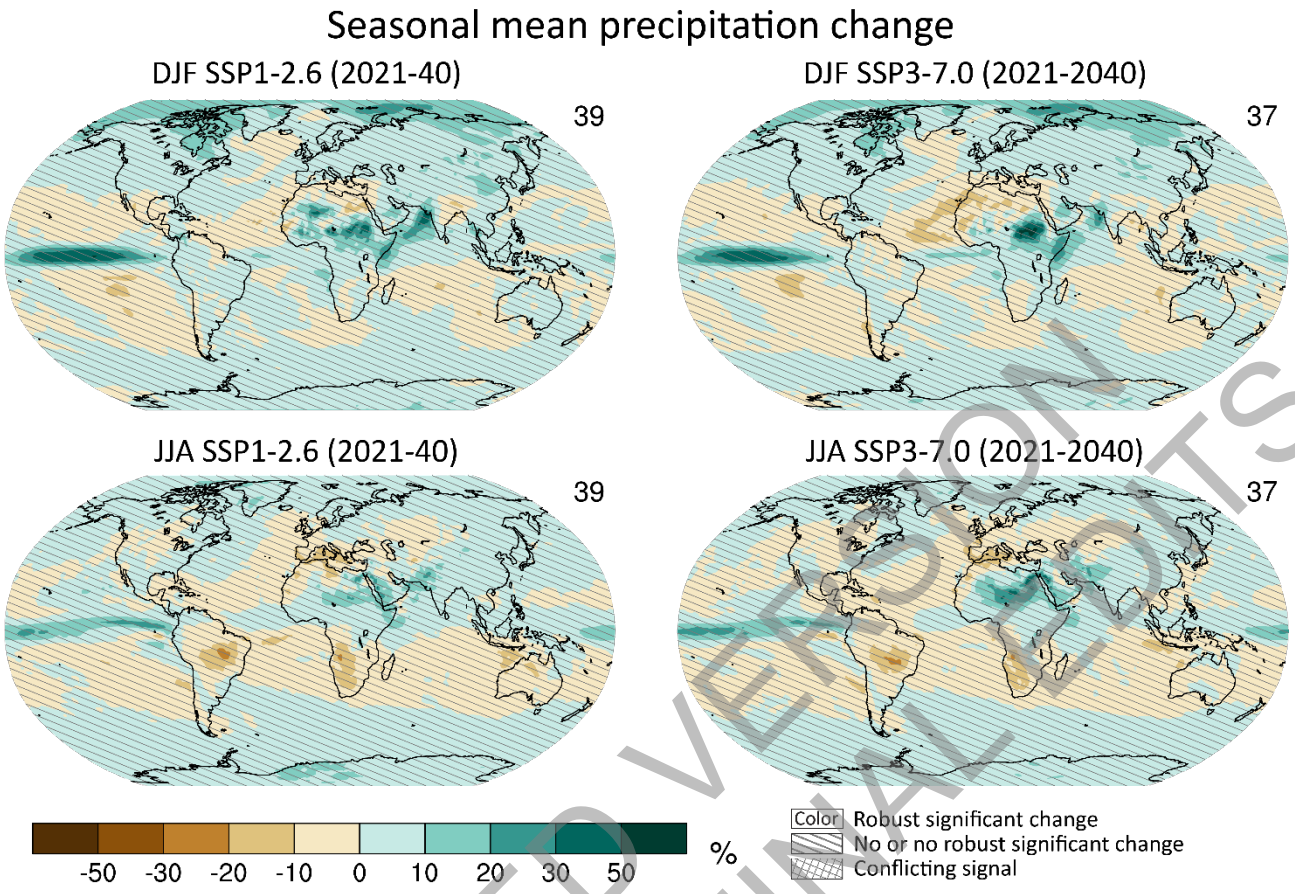

Figure 4.13: Near-term change of seasonal mean precipitation. Displayed are projected spatial patterns of CMIP6 multi-model mean change (%) in (top) DJF and (bottom) JJA precipitation from SSP1-2.6 and SSP3-7.0 in 2021–2040 relative to 1995–2014. The number of models used is indicated in the top right of the maps. No overlay indicates regions where the change is robust and *likely* emerges from internal variability, that is, where at least 66% of the models show a change greater than the internal-variability threshold (see Section 4.2.6) and at least 80% of the models agree on the sign of change. Diagonal lines indicate regions with no change or no robust significant change, where fewer than 66% of the models show change greater than the internal-variability threshold. Crossed lines indicate areas of conflicting signals where at least 66% of the models show change greater than the internal-variability threshold but fewer than 80% of all models agree on the sign of change. Further details on data sources and processing are available in the chapter data table (Table 4.SM.1).

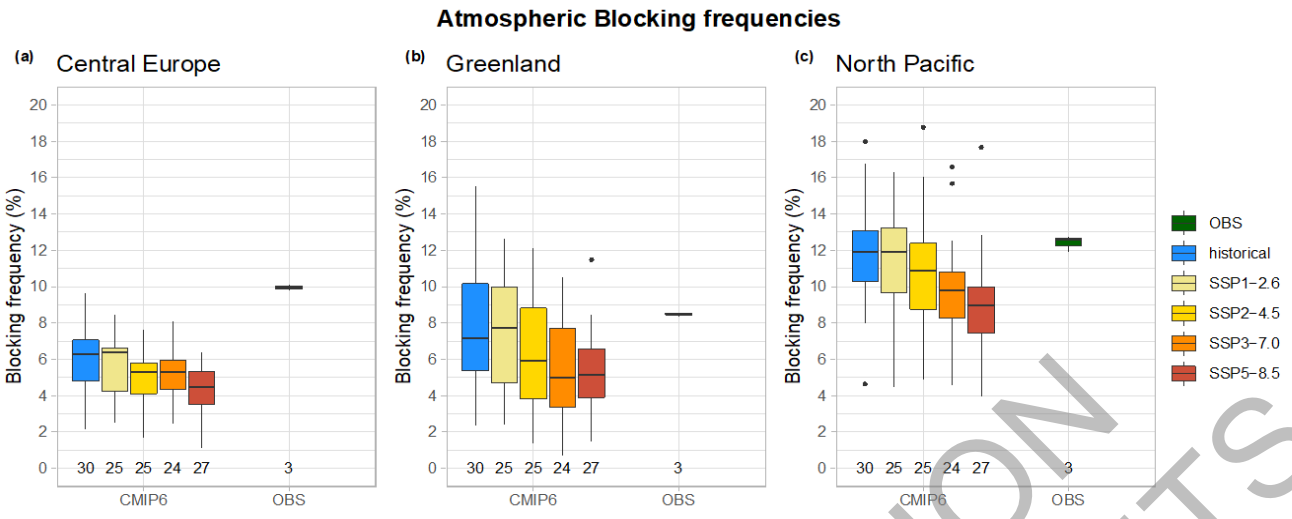

Figure 4.28: Projected wintertime atmospheric blocking frequencies. Box plot showing December-to-March atmospheric blocking frequencies from historical simulations over 1995–2014 and projections over 2081–2100, over (a) the Central European region (20°W–20°E, 45°N–65°N), (b) the Greenland region (65°W–20°W, 62.5°N–72.5°N), (c) the North Pacific region (130°E–150°W, 60°N–75°N). Values show the percentage of blocked days per season following the (Davini et al., 2012) index. Median values are the thick black horizontal bar. The lower whiskers extend from the first quartile to the smallest value in the ensemble, and the upper whiskers extend from the third quartile to the largest value. The whiskers are limited to an upper bound that is 1.5 times the interquartile range (the distance between the third and first quartiles). Black dots show outliers from the whiskers. The numbers below each bar report the number of models included. Observationally based values are obtained as the average of the ERA-Interim Reanalysis, the JRA-55 Reanalysis and the NCEP/NCAR Reanalysis. Adapted from (Davini and D'Andrea, 2020). Further details on data sources and processing are available in the chapter data table (Table 4.SM.1).

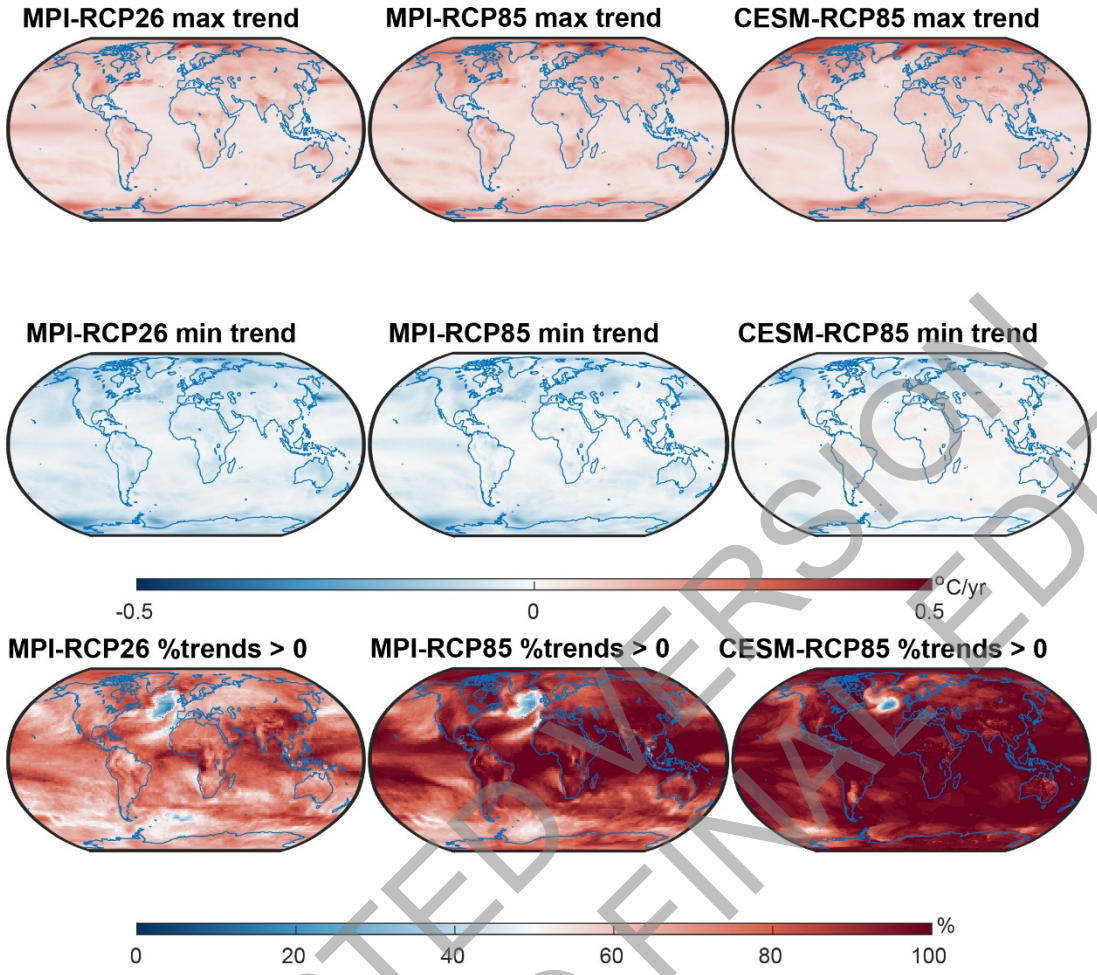

Figure 4.36: Masking of climate response to mitigation by internal variability in the near term. Near-term (2021–2040) pointwise maximum (top row) and pointwise minimum (middle row) surface air temperature trends in the large initial-condition ensemble from MPI (left and centre columns), and CESM (right column) models in the RCP2.6 (left column) and RCP8.5 scenarios (centre and right columns). The percentage of ensemble members with a warming trend in the near term is shown in the bottom panels. Figure modified from (Maher et al., 2020). Further details on data sources and processing are available in the chapter data table (Table 4.SM.1).

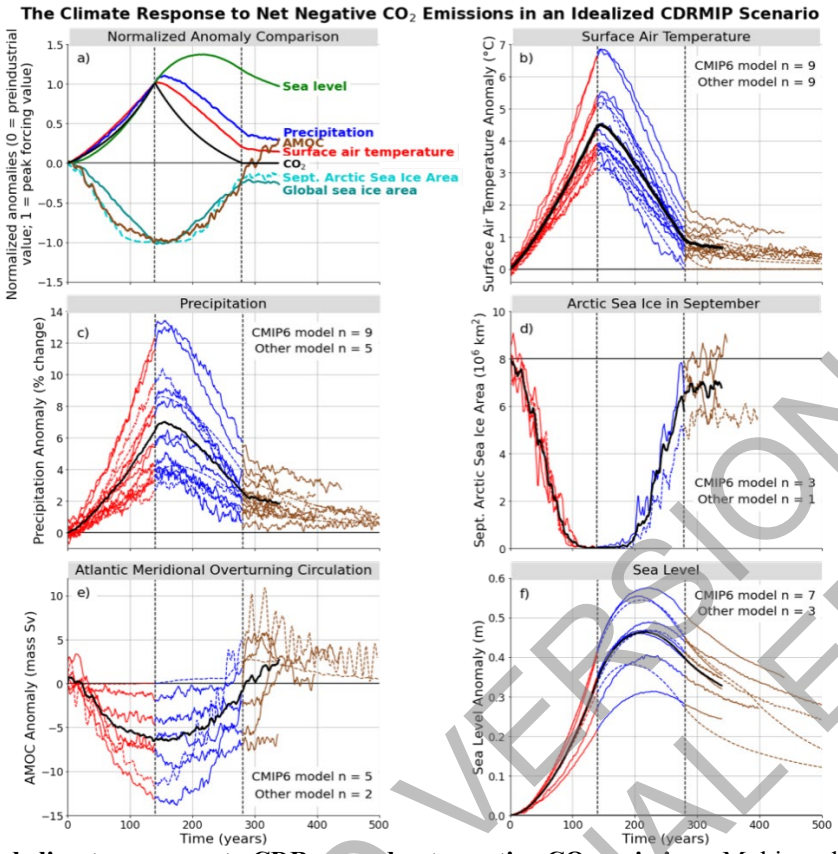
ACCEPTED VERSION SUBJECT TO FINAL EDITS



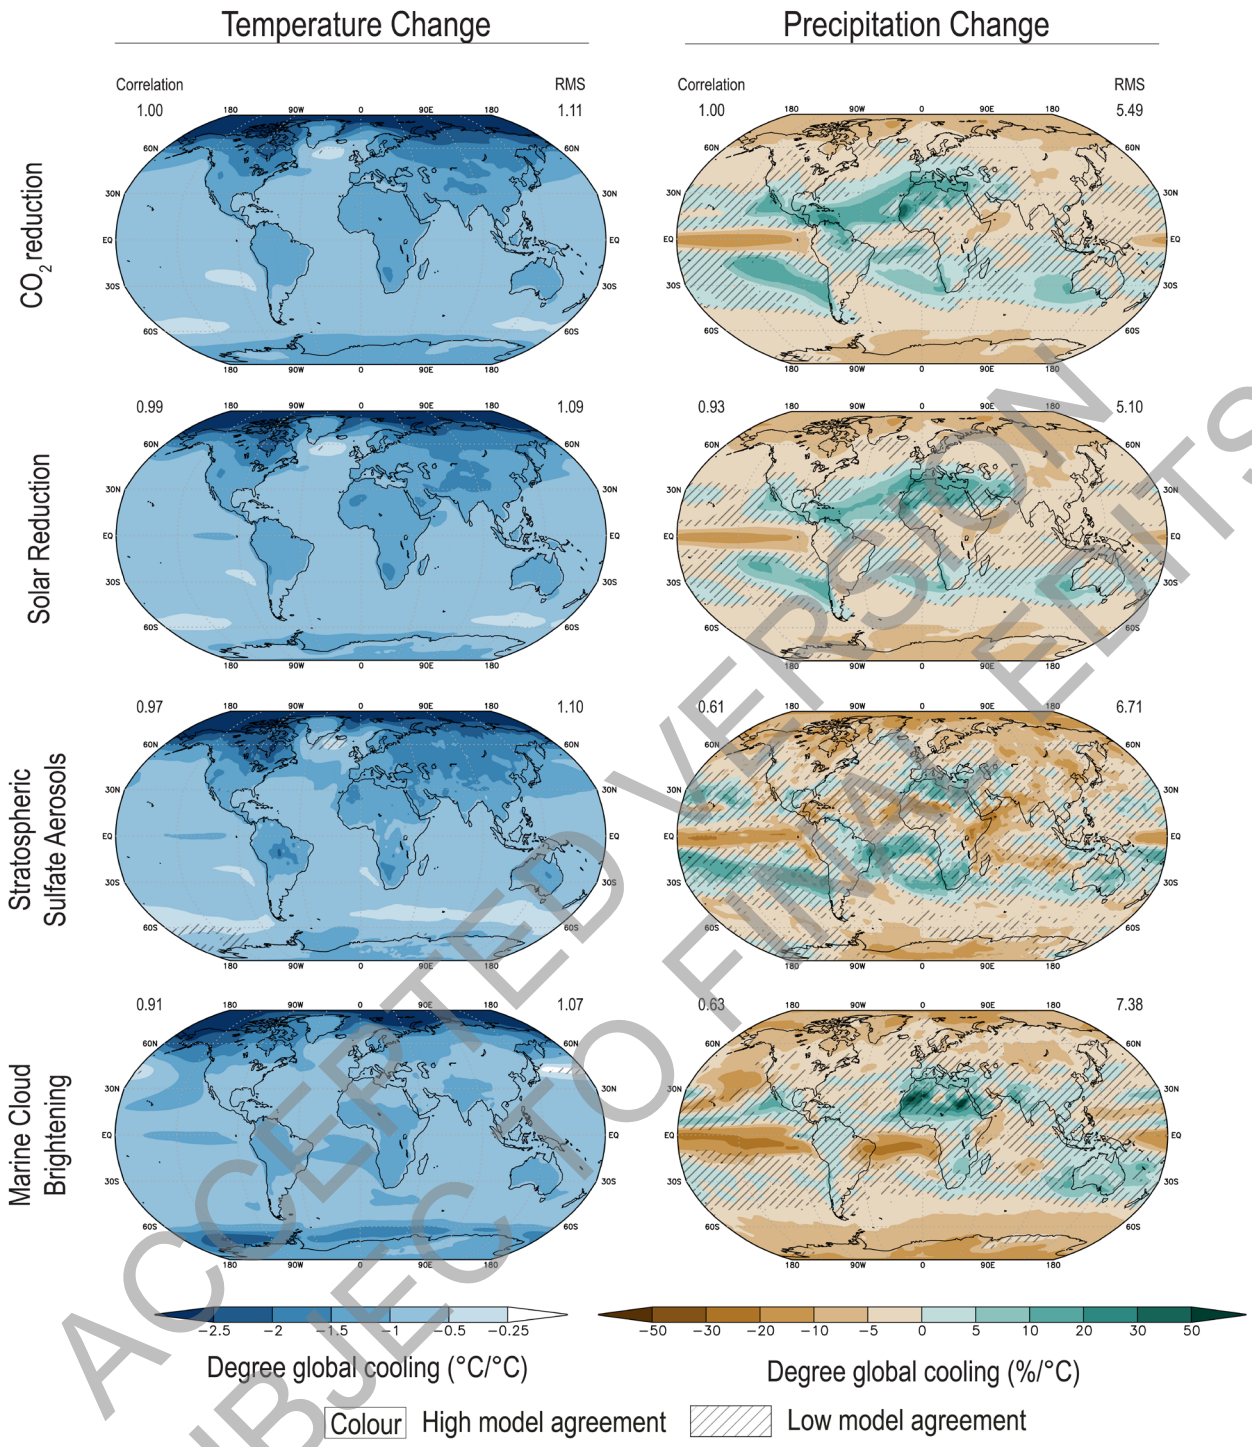


Figure 4.37: Delayed climate response to CDR-caused net negative CO_2 emissions. Multi-model simulated response in global and annual mean climate variables for a ramp-up followed by ramp-down of CO_2. Atmospheric CO_2 increases from the pre-industrial level at a rate of 1% yr^{-1} to 4×CO_2, then decreases at the same rate to the pre-industrial level and then remains constant. The ramp-down phase represents the period of net negative CO_2 emissions. a) normalized ensemble mean anomaly of key variables as a function of year, including atmospheric CO_2, surface air temperature, precipitation, thermosteric sea-level rise (see Glossary), global sea-ice area, Northern Hemisphere sea-ice area in September, and Atlantic meridional overturning circulation (AMOC); b) surface air temperature; c) precipitation; d) September Arctic sea-ice area; e) AMOC; f) thermostatic sea level; 5-year running means are shown for all variables except the sea-level rise. In b–f, red lines represent the phase of CO_2 ramp-up, blue lines represent the phase of CO_2 ramp-down, brown lines represent the period after CO_2 has returned to pre-industrial level, and black lines represent the multi-model mean. For all of the segments in b–f, the solid coloured lines are CMIP6 models, and the dashed lines are other models (i.e., EMICs, CMIP5 era models). Vertical dashed lines indicate peak CO_2 and when CO_2 again reaches pre-industrial value. The number of CMIP6 and non-CMIP6 models used is indicated in each panel. The time series for the multi-model means (b–f) and the normalized anomalies (a) are terminated when data from all models are not available, in order to avoid the discontinuity in the time series. Further details on data sources and processing are available in the chapter data table (Table 4.SM.1).

Figure 4.38: Multi-model response per degree global mean cooling in temperature and precipitation in response to CO_2 forcing and SRM forcing. Top row shows the response to a CO_2 decrease, calculated as the difference between pre-industrial control simulation and abrupt4 • CO_2 simulations where the CO_2 concentration is quadrupled abruptly from the pre-industrial level (11-model average); second row shows the response to a globally uniform solar reduction, calculated as the difference between GeoMIP experiment G1 and abrupt4 • CO_2 (11-model average); third row shows the response to stratospheric sulphate aerosol injection, calculated as the difference between GeoMIP experiment G4 (a continuous injection of 5Tg SO_2 per year at one point on the equator into the lower stratosphere against the RCP4.5 background scenario) and RCP4.5 (6-model average); and bottom row shows the response to marine cloud brightening, calculated as the difference between GeoMIP experiment G4cdnc (increase cloud droplet concentration number in marine low cloud by 50% over the global ocean against RCP4.5 background scenario) and RCP4.5 (8-model average). All differences (average of years 11–50 of

simulation) are normalized by the global mean cooling in each scenario, averaged over years 11–50. Diagonal lines represent regions where fewer than 80% of the models agree on the sign of change. The values of correlation represent the spatial correlation of each SRM-induced temperature and precipitation change pattern with the pattern of change caused by a reduction of atmospheric CO_2. RMS (root mean square) is calculated based on the fields shown in the maps (normalized by global mean cooling). Further details on data sources and processing are available in the chapter data table (Table 4.SM.1).

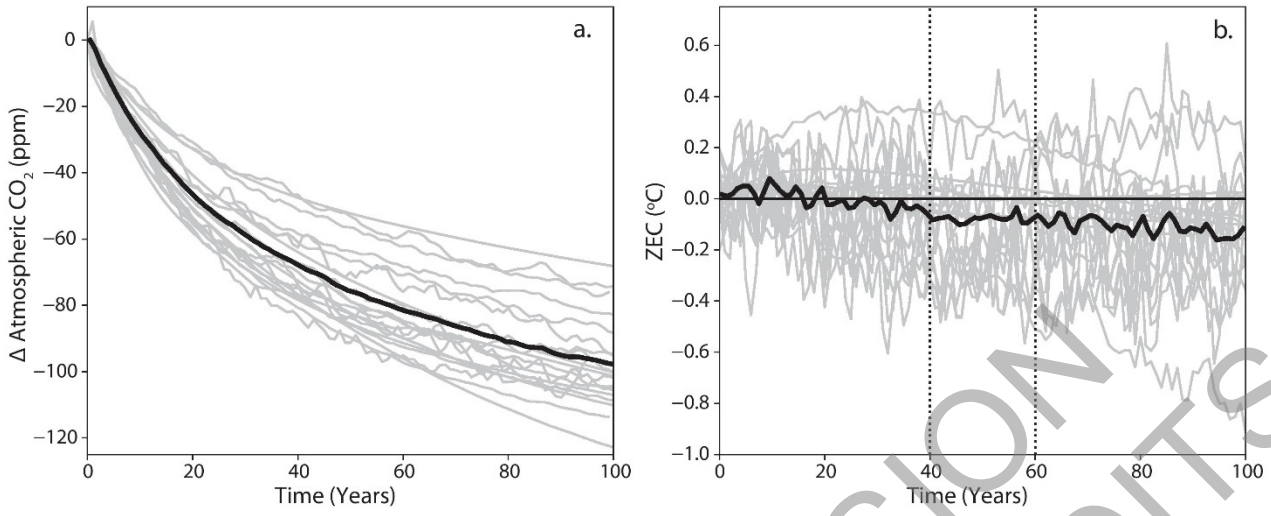

Figure 4.39: Zero Emissions Commitment (ZEC). Changes in (a) atmospheric CO_2 concentration and (b) evolution of GSAT following cessation of CO_2 emissions branched from the 1% per year experiment after emission of 1000 PgC (Jones et al., 2019). ZEC is the temperature anomaly relative to the estimated temperature at the year of cessation. ZEC_{50} is the 20-year mean GSAT change centred on 50 years after the time of cessation (see Table 4.8) – this period is marked with the vertical dotted lines. Multi-model mean is shown as thick black line, individual model simulations are in grey. Further details on data sources and processing are available in the chapter data table (Table 4.SM.1).

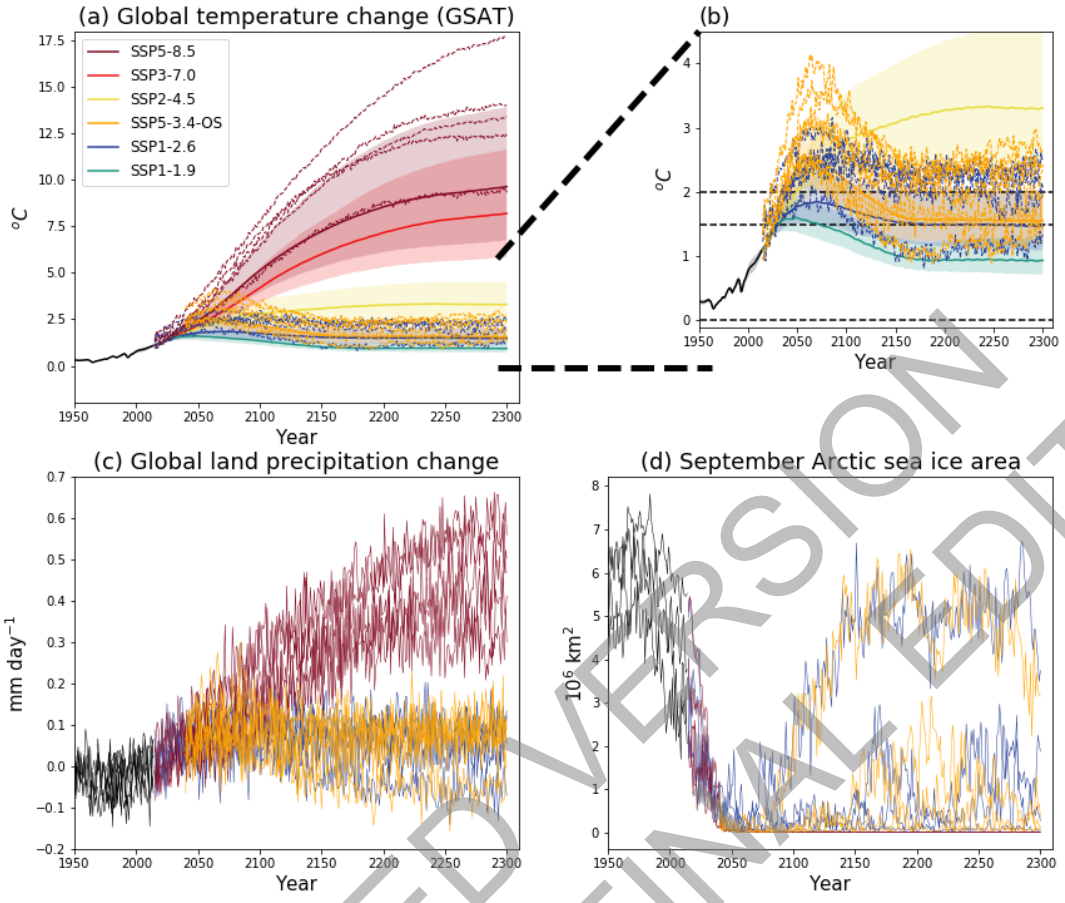

Figure 4.40: Simulated climate changes up to 2300 under the extended SSP scenarios. Displayed are (a) projected GSAT change, relative to 1850–1900, from CMIP6 models (individual lines) and MAGICC7 (shaded plumes), (b) as (a) but zoomed in to show low-emission scenarios, (c) global land precipitation change, and (d) September Arctic sea-ice area. Further details on data sources and processing are available in the chapter data table (Table 4.SM.1).

ACCEPTED VERSION SUBJEC TO FINAL EDITS

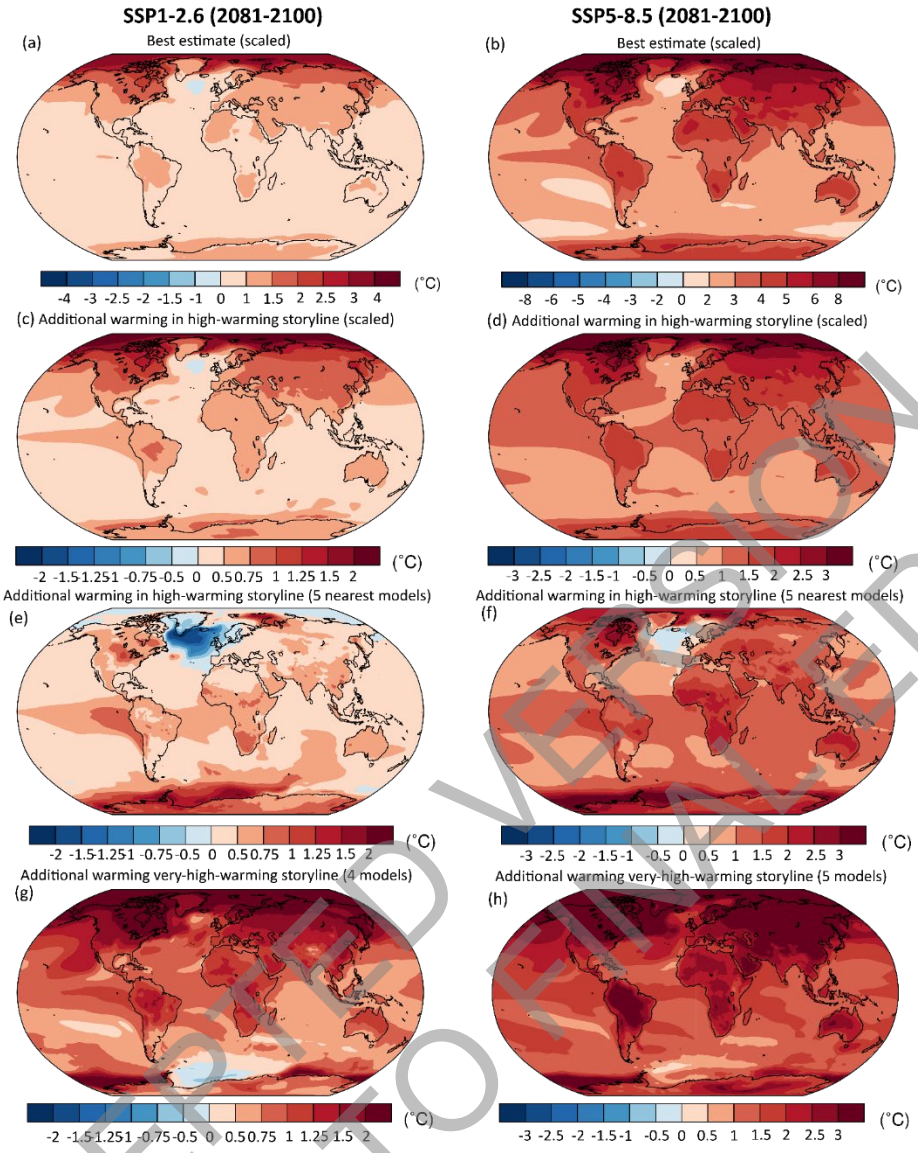

Figure 4.41: High-warming storylines for changes in annual mean temperature. (a, b) Changes in 2081–2100 relative to 1995–2014 consistent with the assessed best GSAT estimate (0.9°C and 3.5°C relative to 1995–2014 for SSP1-2.6 and SSP5-8.5, respectively). The CMIP6 multi-model mean is linearly pattern-scaled to the best GSAT estimate. (c–h) Annual mean warming above the best estimate (relative to panels a and b, respectively, note the different colour bar) in a high and very high-warming storyline for 2081–2100. (c, d) Multi-model mean warming pattern scaled to very high GSAT level corresponding to the upper bound of the assessed *very likely* range (4.8°C for SSP5-8.5 and 1.5°C for SSP1-2.6, see Section 4.3.4). (e, f) Average of five models with high GSAT warming nearest to the upper estimate of the *very likely* range (CESM2, CESM2-WACCM, CNRM-CM6-1, CNRM-CM6-1-HR, EC-Earth3 for SSP1-2.6 and ACCESS-CM2, CESM2, CESM2-WACCM, CNRM-CM6-1, CNRM-CM6-1-HRfor SSP5-8.5), (g, h) Average of four and five models, respectively (ACCESS-CM2, HadGEM3-GC31-LL, HadGEM3-GC31-MM, UKESM1-0-LL for SSP1-2.6 and CanESM5, CanESM5-CanOE, HadGEM3-GC31-LL: HadGEM3-GC31-MM, UKESM1-0-LL for SSP5-8.5) projecting very high GSAT warming exceeding the *very likely* range. Further details on data sources and processing are available in the chapter data table (Table 4.SM.1).

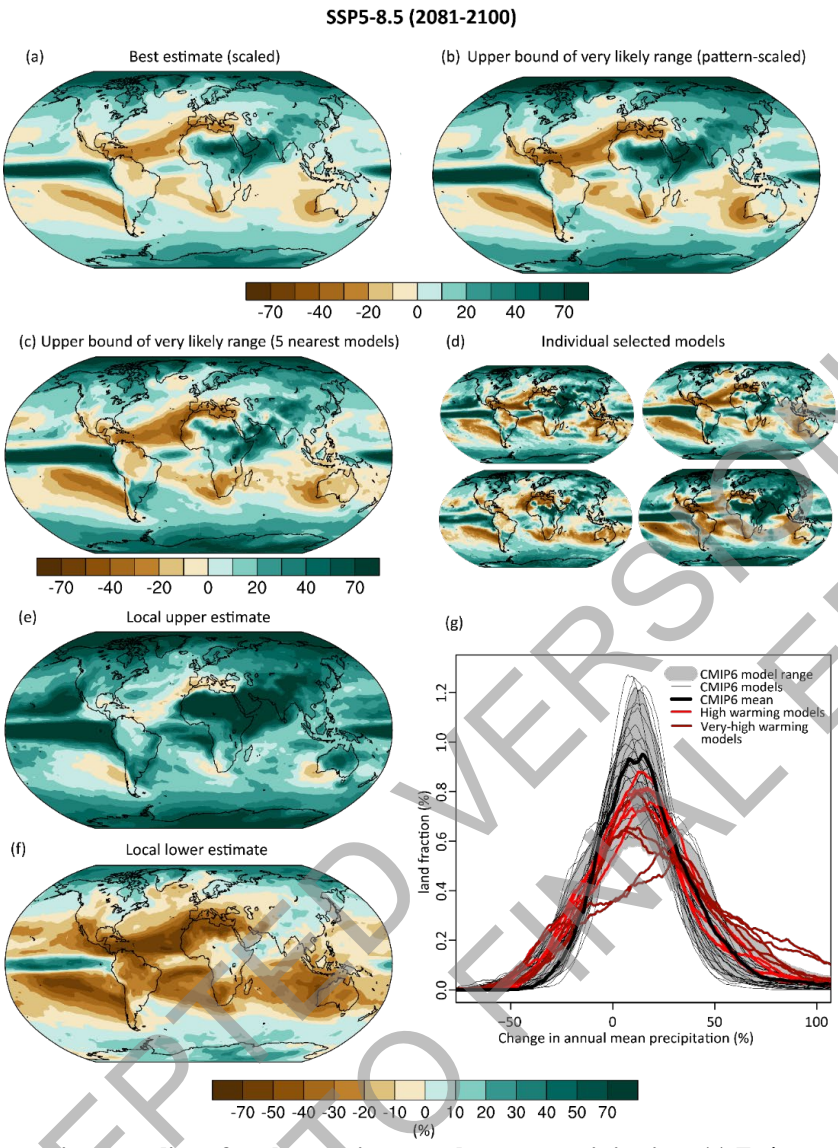
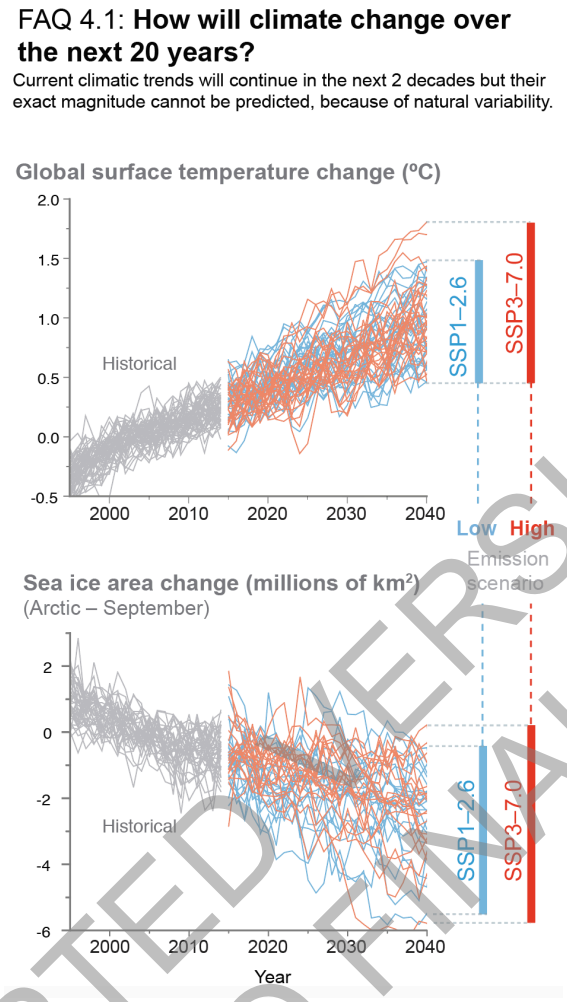
ACCEPTED VERSION SUBJECT TO FINAL EDITS





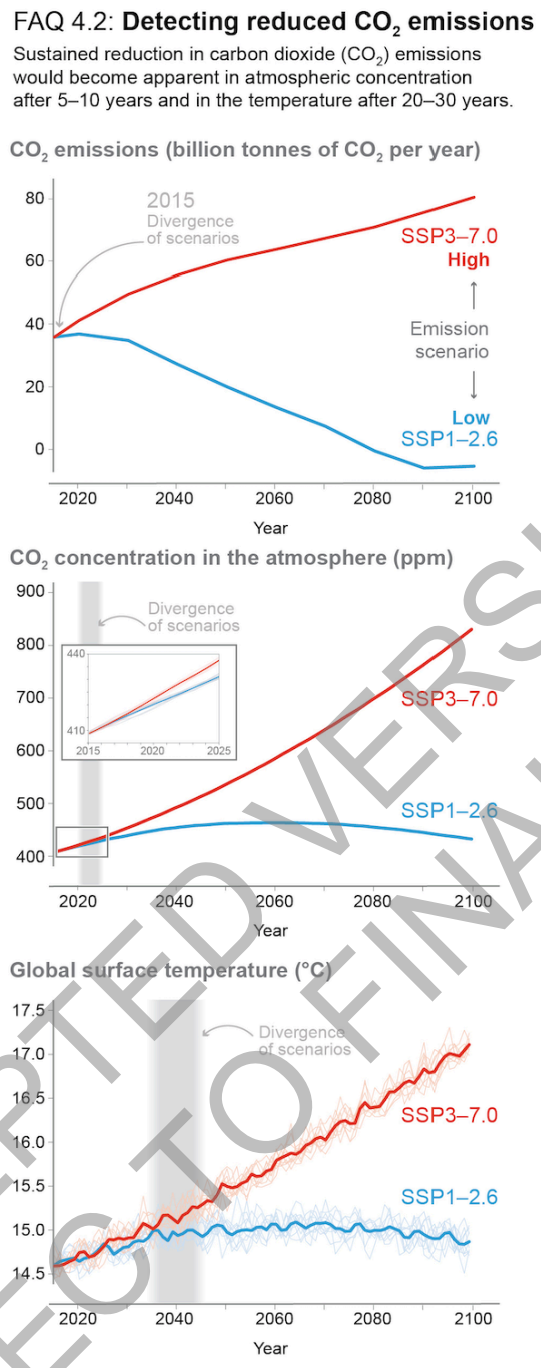


Figure 4.42: High-warming storylines for changes in annual mean precipitation. (a) Estimates for annual mean precipitation changes in 2081–2100 relative 1995–2014, consistent with the best GSAT estimate derived by linearly scaling the CMIP6 multi-model mean changes to a GSAT change of 3.5°C. (b, c) Estimates for annual mean precipitation changes in 2081–2100 relative 1995–2014 in a storyline representing a physically plausible high-global-warming level. (b) Multi-model mean precipitation scaled to high-global-warming level (corresponding to 4.8°C, the upper bound of the *very likely* range, see Section 4.3.4). (c) Average of five models with GSAT warming nearest to the high level of warming (ACCESS-CM2, CESM2, CESM2-WACCM, CNRM-CM6-1, CNRM-CM6-1-HR) (d) Annual mean precipitation changes in four of the five individual model simulations averaged in (c). (e, f) Local upper estimate (95% quantile across models) and lower estimate (5% quantile across models) at each grid point. Information at individual grid points comes from different model simulations and illustrates local uncertainty range but should not be interpreted as a pattern. (g) Area fraction of changes in annual mean precipitation 2081–2100 relative to 1995–2014 for all CMIP6 model simulations (thin black lines), models shown in (c) (red lines), and models showing very high warming above the models shown in (c). The grey range illustrates the 5–95% range across CMIP6 models and the solid black line the area fraction of the multi-model mean pattern shown in (a). Further details on data sources and processing are available in the chapter data table (Table 4.SM.1).

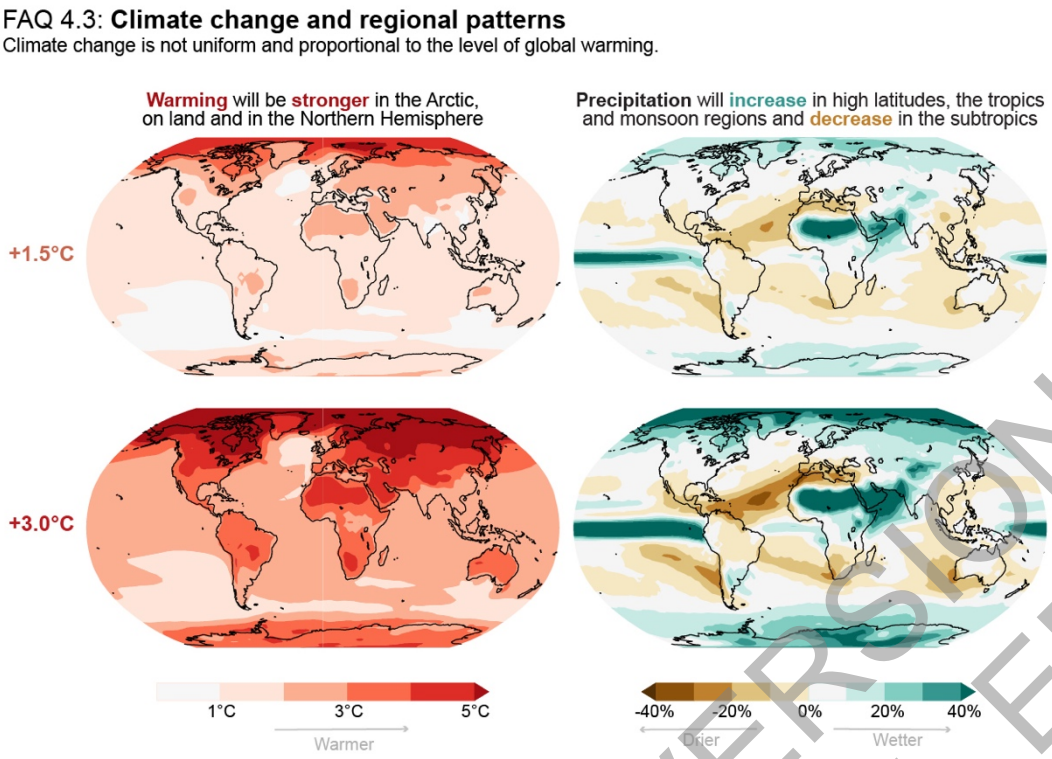
ACCEPTED VERSION SUBJECT TO FINAL EDITS



FAQ 4.1, Figure 1: Simulations over the period 1995–2040, encompassing the recent past and the next twenty years, of two important indicators of global climate change. (top) global surface temperature, and (bottom), the area of Arctic sea ice in September. Both quantities are shown as deviations from the average over the period 1995–2014. The black curves are for the historical period ending in 2014; the blue curves represent a low-emission scenario (SSP1-2.6) and the red curves one high-emission scenario (SSP3-7.0).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

FAQ 4.2, Figure 1: Observing the benefits of emission reductions. (top) Carbon dioxide (CO_2) emissions, (middle) CO_2 concentration in the atmosphere and (bottom) effect on global surface temperature for two scenarios: a low-emission scenario (SSP1-2.6, blue) and a high-emission scenario (SSP3-7.0). In the low-emission scenario, CO_2 emissions begin to decrease in 2020 whereas they keep increasing throughout the 21st century in the high-emission scenario. The thick lines are the average of the ten individual simulations (thin line) for each scenario. Differences between individual simulations reflect natural variability.

ACCEPTED VERSION SUBJECT TO FINAL EDITS

FAQ 4.3, Figure 1: Regional changes in temperature (left) and precipitation (right) are proportional to the level of global warming, irrespective of the scenario through which the level of global warming is reached. Surface warming and precipitation change are shown relative to the 1850–1900 climate, and for time periods over which the globally averaged surface warming is 1.5°C (top) and 3°C (bottom), respectively. Changes presented here are based on thirty-one CMIP6 models using the high-emission scenario SSP3-7.0.

Executive Summary

It is unequivocal that emissions of the well-mixed greenhouse gases (GHG) carbon dioxide (CO_2), methane (CH_4) and nitrous oxide (N_2O) from human activities are the main driver of increases in atmospheric GHG concentrations since the pre-industrial period. The accumulation of GHGs in the atmosphere is determined by the balance between anthropogenic emissions, anthropogenic removals, and physical-biogeochemical source and sink dynamics on land and in the ocean. This chapter assesses how physical and biogeochemical processes of the carbon and nitrogen cycles affect the variability and trends of GHGs in the atmosphere as well as ocean acidification and deoxygenation. It identifies physical and biogeochemical feedbacks that have affected or could affect future rates of GHG accumulation in the atmosphere, and therefore, influence climate change and its impacts. This chapter also assesses the remaining carbon budget to limit global warming within various goals, as well as the large-scale consequences of carbon dioxide removal (CDR) and solar radiation modification (SRM) on biogeochemical cycles {Figures 5.1, 5.2}.

The Human Perturbation of the Carbon and Biogeochemical cycles

Global mean concentrations for well-mixed GHGs (CO_2, CH_4 and N_2O) in 2019 correspond to increases of about 47%, 156%, and 23%, respectively, above the levels in 1750 (representative of the pre-industrial) (*high confidence*). Current atmospheric concentrations of the three GHGs are higher than at any point in the last 800,000 years, and in 2019 reached 409.9 ppm of CO_2, 1866.3 ppb of CH_4, and 332.1 ppb of N_2O (*very high confidence*). Current CO_2 concentrations in the atmosphere are also unprecedented in the last 2 million years (*high confidence*). In the past 60 Myr, there have been periods in Earth's history when CO_2 concentrations were significantly higher than at present, but multiple lines of evidence show that the rate at which CO_2 has increased in the atmosphere during 1900–2019 is at least 10 times faster than at any other time during the last 800,000 years (*high confidence*), and 4-5 times faster than during the last 56 million years (*low confidence*). {5.1.1, 2.2.3; Figures 5.3, 5.4; Cross-Chapter Box 2.1}

Contemporary Trends of Greenhouse Gases

It is unequivocal that the increase of CO_2, CH_4, and N_2O in the atmosphere over the industrial era is the result of human activities (*very high confidence*). This assessment is based on multiple lines of evidence including atmospheric gradients, isotopes, and inventory data. During the last measured decade, global average annual anthropogenic emissions of CO_2, CH_4, and N_2O, reached the highest levels in human history at 10.9 ± 0.9 PgC yr^{-1} (2010–2019), 335–383 Tg CH_4 yr^{-1} (2008–2017), and 4.2–11.4 TgN yr^{-1} (2007–2016), respectively (*high confidence*). {5.2.1, 5.2.2, 5.2.3, 5.2.4; Figures 5.6, 5.13, 5.15}.

The CO_2 emitted from human activities during the decade of 2010–2019 (decadal average 10.9 ± 0.9 PgC yr^{-1}) was distributed between three Earth system components: 46% accumulated in the atmosphere (5.1 ± 0.02 PgC yr^{-1}), 23% was taken up by the ocean (2.5 ± 0.6 PgC yr^{-1}) and 31% was stored by vegetation in terrestrial ecosystems (3.4 ± 0.9 PgC yr^{-1}) (*high confidence*). Of the total anthropogenic CO_2 emissions, the combustion of fossil fuels was responsible for 81–91%, with the remainder being the net CO_2 flux from land-use change and land management (e.g., deforestation, degradation, regrowth after agricultural abandonment or peat drainage). {5.2.1.2, 5.2.1.5; Table 5.1; Figures 5.5, 5.7, 5.12}

Over the past six decades, the average fraction of anthropogenic CO_2 emissions that has accumulated in the atmosphere (referred to as the airborne fraction) has remained nearly constant at approximately 44%. The ocean and land sinks of CO_2 have continued to grow over the past six decades in response to increasing anthropogenic CO_2 emissions (*high confidence)*. Interannual and decadal variability of the regional and global ocean and land sinks indicate that these sinks are sensitive to climate conditions and therefore to climate change (*high confidence*). {5.2.1.1, 5.2.1.3, 5.2.1.4.2; Figures 5.7, 5.8, 5.10}

Recent observations show that ocean carbon processes are starting to change in response to the growing ocean sink, and these changes are expected to contribute significantly to future weakening of the ocean sink under medium- to high-emission scenarios. However, the effects of these changes is not

ACCEPTED VERSION SUBJECT TO FINAL EDITS

yet reflected in a weakening trend of the contemporary (1960–2019) ocean sink (*high confidence*). {5.1.2, 5.2.1.3, 5.3.2.1; Figures 5.8, 5.20; Cross-Chapter Box 5.3}

Atmospheric concentration of CH_4 grew at an average rate of 7.6 ± 2.7 ppb yr^{-1} for the last decade (2010–2019), with a faster growth of 9.3 ± 2.4 ppb yr^{-1} over the last six years (2014–2019) (*high confidence*). The multi-decadal growth trend in atmospheric CH_4 is dominated by anthropogenic activities (*high confidence*), and the growth since 2007 is largely driven by emissions from both fossil fuels and agriculture (dominated by livestock) sectors (*medium confidence)*. The interannual variability is dominated by El Niño–Southern Oscillation cycles, during which biomass burning and wetland emissions, as well as loss by reaction with tropospheric hydroxyl radical OH play an important role. {5.2.2; Figures 5.13, 5.14; Table 5.2; Cross-Chapter Box 5.2}

Atmospheric concentration of N_2O grew at an average rate of 0.85 ± 0.03 ppb yr^{-1} between 1995 and 2019, with a further increase to 0.95 ± 0.04 ppb yr^{-1} in the most recent decade (2010–2019). This increase is dominated by anthropogenic emissions, which have increased by 30% between the 1980s and the most recent observational decade (2007–2016) (*high confidence*). Increased use of nitrogen fertilizer and manure contributed to about two-thirds of the increase during the 1980–2016 period, with the fossil fuels/industry, biomass burning, and wastewater accounting for much of the rest (*high confidence*). {5.2.3; Figures 5.15, 5.16, 5.17}

Ocean Acidification and Ocean Deoxygenation

Ocean acidification is strengthening as a result of the ocean continuing to take up CO_2 from human-caused emissions (*very high confidence*). This CO_2 uptake is driving changes in seawater chemistry that result in the decrease of pH and associated reductions in the saturation state of calcium carbonate, which is a constituent of skeletons or shells of a variety of marine organisms. These trends of ocean acidification are becoming clearer globally, with a *very likely* rate of decrease in pH in the ocean surface layer of 0.016 to 0.020 per decade in the subtropics and 0.002 to 0.026 per decade in subpolar and polar zones since the 1980s. Ocean acidification has spread deeper in the ocean, surpassing 2000 m depth in the northern North Atlantic and in the Southern Ocean. The greater projected pH declines in CMIP6 models are primarily a consequence of higher atmospheric CO_2 concentrations in the Shared Socio-economic Pathways (SSPs) scenarios than their CMIP5-RCP analogues {5.3.2.2, 5.3.3.1; 5.3.4.1; Figures 5.20, 5.21}

Ocean deoxygenation is projected to continue to increase with ocean warming (*high confidence*). Earth system models (ESMs) project a 32–71% greater subsurface (100–600 m) oxygen decline, depending on scenario, than reported in the Special Report on the Ocean and Cryosphere (SROCC) for the period 2080–2099. This is attributed to the effect of larger surface warming in CMIP6 models, which increases ocean stratification and reduces ventilation (*medium confidence*). There is *low confidence* in the projected reduction of oceanic N_2O emissions under high emission scenarios because of greater oxygen losses simulated in ESMs in CMIP6, uncertainties in the process of oceanic N_2O emissions, and a limited number of modelling studies available {5.3.3.2; 7.5}

Future Projections of Carbon Feedbacks on Climate Change

Oceanic and terrestrial carbon sinks are projected to continue to grow with increasing atmospheric concentrations of CO_2, but the fraction of emissions taken up by land and ocean is expected to decline as the CO_2 concentration increases (*high confidence*). ESMs suggest approximately equal global land and ocean carbon uptake for each of the SSPs scenarios. However, the range of model projections is much larger for the land carbon sink. Despite the wide range of model responses, uncertainty in atmospheric CO_2 by 2100 is dominated by future anthropogenic emissions rather than uncertainties related to carbon–climate feedbacks (*high confidence*). {5.4.5; Figure 5.25, 5.26}

Increases in atmospheric CO_2 lead to increases in land carbon storage through CO_2 fertilization of photosynthesis and increased water use efficiency (*high confidence*). However, the overall change in land carbon also depends on land-use change and on the response of vegetation and soil to continued warming

ACCEPTED VERSION SUBJECT TO FINAL EDITS

and changes in the water cycle, including increased droughts in some regions that will diminish the sink capacity. Climate change alone is expected to increase land carbon accumulation in the high latitudes (not including permafrost), but also to lead to a counteracting loss of land carbon in the tropics (*medium confidence*, Figure 5.25). More than half of the latest CMIP6 ESMs include nutrient limitations on the carbon cycle, but these models still project increasing tropical land carbon (*medium confidence*) and increasing global land carbon (*high confidence*) through the 21st century. {5.4.1, 5.4.3, 5.4.5; Figure 5.27; Cross-Chapter Box 5.1}

Future trajectories of the ocean CO_2 sink are strongly emissions-scenario dependent (*high confidence*). Emission scenarios SSP4-6.0 and SSP5-8.5 lead to warming of the surface ocean and large reductions of the buffering capacity, which will slow the growth of the ocean sink after 2050. Scenario SSP1-2.6 limits further reductions in buffering capacity and warming, and the ocean sink weakens in response to the declining rate of increasing atmospheric CO_2. There is *low confidence* in how changes in the biological pump will influence the magnitude and direction of the ocean carbon feedback. {5.4.2, 5.4.4, Cross-Chapter Box 5.3}

Beyond 2100, land and ocean may transition from being a carbon sink to a source under either very high emissions or net negative emissions scenarios, but for different reasons. Under very high emissions scenarios such as SSP5-8.5, ecosystem carbon losses due to warming lead the land to transition from a carbon sink to a source (*medium confidence*), while the ocean is expected to remain a sink (*high confidence*). For scenarios in which CO_2 concentration stabilizes, land and ocean carbon sinks gradually take up less carbon as the increase in atmospheric CO_2 slows down. In scenarios with moderate net negative CO_2 emissions and CO_2 concentrations declining during the 21st century (e.g., SSP1-2.6), the land sink transitions to a net source in decades to a few centuries after CO_2 emissions become net negative, while the ocean remains a sink (*low confidence*). Under scenarios with large net negative CO_2 emissions and rapidly declining CO_2 concentrations (e.g., SSP5-3.4-OS (overshoot)), both land and ocean switch from a sink to a transient source during the overshoot period (*medium confidence*). {5.4.10, 5.6.2.1.2; Figures 5.30, 5.33}

Thawing terrestrial permafrost will lead to carbon release (*high confidence*), but there is *low confidence* in the timing, magnitude and the relative roles of CO_2 versus CH_4 as feedback processes. CO_2 release from permafrost is projected to be 3–41 PgC per 1ºC of global warming by 2100, based on an ensemble of models. However, the incomplete representation of important processes such as abrupt thaw, combined with weak observational constraints, only allow *low confidence* in both the magnitude of these estimates and in how linearly proportional this feedback is to the amount of global warming. It is *very unlikely* that gas clathrates in terrestrial and subsea permafrost will lead to a detectable departure from the emissions trajectory during this century. {5.4.9; Box 5.1}

The net response of natural CH_4 and N_2O sources to future warming will be increased emissions (*medium confidence*). Key processes include increased CH_4 emissions from wetlands and permafrost thaw, as well as increased soil N_2O emissions in a warmer climate, while ocean N_2O emissions are projected to decline at centennial time scale. The magnitude of the responses of each individual process and how linearly proportional these feedbacks are to the amount of global warming is known with *low confidence* due to incomplete representation of important processes in models combined with weak observational constraints. Models project that over the 21st century the combined feedback of 0.02–0.09 W m^{-2} $°C^{-1}$ is comparable to the effect of a CO_2 release of 5-18 PgCeq $°C^{-1}$ (*low confidence*). {5.4.7, 5.4.8; Figure 5.29}

The response of biogeochemical cycles to the anthropogenic perturbation can be abrupt at regional scales, and irreversible on decadal to century time scales (*high confidence*). The probability of crossing uncertain regional thresholds (e.g., high severity fires, forest dieback) increases with climate change (*high confidence*). Possible abrupt changes and tipping points in biogeochemical cycles lead to additional uncertainty in 21st century GHG concentrations, but these are *very likely* to be smaller than the uncertainty associated with future anthropogenic emissions (*high confidence*). {5.4.9}

Remaining Carbon Budgets to Climate Stabilization

There is a near-linear relationship between cumulative CO_2 emissions and the increase in global mean

ACCEPTED VERSION SUBJECT TO FINAL EDITS

surface air temperature (GSAT) caused by CO_2 over the course of this century for global warming levels up to at least 2°C relative to pre-industrial (*high confidence*). Halting global warming would thus require global net anthropogenic CO_2 emissions to become zero. The ratio between cumulative CO_2 emissions and the consequent GSAT increase, which is called the transient climate response to cumulative emissions of CO_2 (TCRE), *likely* falls in the 1.0°C–2.3°C per 1000 PgC range. The narrowing of this range compared to AR5 is due to a better integration of evidence across the science in this assessment. Beyond this century, there is *low confidence* that the TCRE remains an accurate predictor of temperature changes in scenarios of very low or net negative CO_2 emissions because of uncertain Earth system feedbacks that can result in further warming or a path-dependency of warming as a function of cumulative CO_2 emissions. {5.4, 5.5.1}

Mitigation requirements over this century for limiting maximum warming to specific levels can be quantified using a carbon budget that relates cumulative CO_2 emissions to global mean temperature increase (*high confidence*). For the period 1850–2019, a total of 655 ± 65 PgC (2390 ± 240 $GtCO_2$) of anthropogenic CO_2 has been emitted. Remaining carbon budgets (starting from 1 January 2020) for limiting warming to 1.5°C, 1.7°C, and 2.0°C are 140 PgC (500 $GtCO_2$), 230 PgC (850 $GtCO_2$) and 370 PgC (1350 $GtCO_2$), respectively, based on the 50th percentile of TCRE. For the 67th percentile, the respective values are 110 PgC (400 $GtCO_2$), 190 PgC (700 $GtCO_2$) and 310 PgC (1150 $GtCO_2$). These remaining carbon budgets may vary by an estimated ± 60 PgC (220 $GtCO_2$) depending on how successfully future non-CO_2 emissions can be reduced. Since AR5 and SR1.5, estimates have undergone methodological improvements, resulting in larger, yet consistent estimates. {5.5.2, 5.6; Figure 5.31; Table 5.8}

Several factors affect the precise value of remaining carbon budgets, including estimates of historical warming, future emissions from thawing permafrost, and variations in projected non-CO_2 warming. Remaining carbon budget estimates can increase or decrease by 150 PgC (550 $GtCO_2$, *likely* range) due to uncertainties in the level of historical warming, and by an additional ± 60 PgC (±220 GtCO, *likely* range) due to geophysical uncertainties surrounding the climate response to non-CO_2 emissions such as CH_4, N_2O, and aerosols. Permafrost thaw is included in the estimates together with other feedbacks that are often not captured by models. Despite the large uncertainties surrounding the quantification of the effects of additional Earth system feedback processes, such as emissions from wetlands and permafrost thaw, these feedbacks represent identified additional amplifying risk factors that scale with additional warming and mostly increase the challenge of limiting warming to specific temperature thresholds. These uncertainties do not change the basic conclusion that global CO_2 emissions would need to decline to at least net zero to halt global warming. {5.4, 5.5.2}

Biogeochemical Implications of Carbon Dioxide Removal and Solar Radiation Modification

Land- and ocean-based carbon dioxide removal (CDR) methods have the potential to sequester CO_2 from the atmosphere, but the benefits of this removal would be partially offset by CO_2 release from land and ocean carbon stores (*very high confidence*). The fraction of CO_2 removed that remains out of the atmosphere, a measure of CDR effectiveness, decreases slightly with increasing amount of removal (*medium confidence*) and decreases strongly if CDR is applied at lower CO_2 concentrations (*medium confidence*). {5.6.2.1; Figures 5.32, 5.33, 5.34}

The century-scale climate–carbon cycle response to a CO_2 removal from the atmosphere is not always equal and opposite to the response to a CO_2 emission (*medium confidence*). For simultaneously cumulative CO_2 emissions and removals of greater than or equal to 100 PgC, CO_2 emissions are 4 ± 3% more effective at raising atmospheric CO_2 than CO_2 removals are at lowering atmospheric CO_2. The asymmetry originates from state-dependencies and non-linearities in carbon cycle processes and implies that an extra amount of CDR is required to compensate for a positive emission of a given magnitude to attain the same change in atmospheric CO_2. The net effect of this asymmetry on the global surface temperature is poorly constrained due to *low agreement* between models (*low confidence*). {5.6.2.1; Figure 5.35}

Wide-ranging side-effects of CDR methods have been identified that can either weaken or strengthen the carbon sequestration and cooling potential of these methods and affect the achievement of

ACCEPTED VERSION SUBJECT TO FINAL EDITS

sustainable development goals (*high confidence*). Biophysical and biogeochemical side-effects of CDR methods are associated with changes in surface albedo, the water cycle, emissions of CH_4 and N_2O, ocean acidification and marine ecosystem productivity (*high confidence*). These side-effects and associated Earth system feedbacks can decrease carbon uptake and/or change local and regional climate, and in turn limit the CO_2 sequestration and cooling potential of specific CDR methods (*medium confidence*). Deployment of CDR, particularly on land, can also affect water quality and quantity, food production and biodiversity, with consequences for the achievement of related sustainable development goals (*high confidence*). These effects are often highly dependent on local context, management regime, prior land use, and scale of deployment (*high confidence*). A wide range of co-benefits are obtained with methods that seek to restore natural ecosystems or improve soil carbon (*high confidence*). The biogeochemical effects of terminating CDR are expected to be small for most CDR methods (*medium confidence*). {5.6.2.2; Figure 5.36; Cross-Chapter Box 5.1}

Solar radiation modification (SRM) would increase the global land and ocean CO_2 sinks (*medium confidence*) but would not stop CO_2 from increasing in the atmosphere, thus exacerbating ocean acidification under continued anthropogenic emissions (*high confidence*). SRM acts to cool the planet relative to unmitigated climate change, which would increase the land sink by reducing plant and soil respiration and slow the reduction of ocean carbon uptake due to warming (*medium confidence*). SRM would not counteract or stop ocean acidification (*high confidence*). The sudden and sustained termination of SRM would rapidly increase global warming, with the return of positive and negative effects on the carbon sinks (*very high confidence*) {4.6.3; 5.6.3}

SUBJECT TO FINAL EDITS

5.1 Introduction

The physical and biogeochemical controls of greenhouse gases (GHGs) is a central motivation for this chapter, which identifies biogeochemical feedbacks that have led or could lead to a future acceleration, slowdown or abrupt transitions in the rate of GHG accumulation in the atmosphere, and therefore of climate change. A characterisation of the trends and feedbacks lead to improved quantification for the remaining carbon budgets for climate stabilisation, and the responses of the carbon cycle to atmospheric CO_2 removal, which is embedded in many of the mitigation scenarios, to achieve the goals of the Paris Agreement.

Changes in the abundance of well-mixed GHGs (carbon dioxide (CO_2), methane (CH_4) and nitrous oxide (N_2O)) in the atmosphere play a large role in determining the Earth's radiative properties and its climate in the past, the present and the future (Chapters 2, 4, 6 and 7). Since 1950, the increase in atmospheric GHGs has been the dominant cause of the human-induced climate change (Section 3.3). While the main driver of changes in atmospheric GHGs over the past 200 years relate to the direct emissions from human activities, the net accumulation of GHGs in the atmosphere is controlled by biogeochemical source-sink dynamics of carbon that exchange between multiple reservoirs on land, oceans and atmosphere. The combustion of fossil fuels and land use change for the period 1750–2019 have released an estimated 700 ± 75 PgC (1 PgC = 10^{15} g of carbon) to the atmosphere of which less than half remains in the atmosphere today (Sections 5.2.1.2; 5.2.1.5) (Friedlingstein et al., 2020). This underscores the central role of terrestrial and ocean CO_2 sinks in regulating its atmospheric concentration (Ballantyne et al., 2012; Li et al., 2016c; Le Quéré et al., 2018a; Ciais et al., 2019; Gruber et al., 2019a; Friedlingstein et al., 2020).

The chapter covers three dominant GHGs in the human perturbation of the Earth's radiation budget for which high quality records exist: carbon dioxide (CO_2), methane (CH_4) and nitrous oxide (N_2O) (Figure 5.1).

Section 5.1 (this section) provides the time context on how unique current and future scenarios of GHGs atmospheric concentrations and growth rates are in the Earth's history. It also introduces the main processes involved in carbon-climate feedbacks followed by an assessment of what can be learned from the paleo record towards a better understanding of contemporary and future GHGs-climate dynamics and their response to different mitigation trajectories.

Section 5.2 covers the state of the carbon cycle and other biogeochemical cycles, and global budgets of CO_2, CH_4 and N_2O for the industrial era (since 1750). The section emphasises the last 60-year period for which high-resolution observations are available and the most recent decade for comprehensive GHGs budgets. Significant advances have taken place since the IPCC fifth assessment report (AR5), particularly in constraining the annual to decadal variability of the ocean and land carbon sources and sinks, and in revealing about the sensitivity of carbon pools to current and future climate changes. There has been an important increase in modelling capability of the three GHGs both for land and oceans, atmospheric and ocean observations, and remote sensing products that has enabled to constrain the causes of the observed trends and variability.

Section 5.3 builds on SROCC covering the change in ocean acidification due to oceanic CO_2 uptake across the paleo, historical periods and future projections using CMIP6, with consequences for marine life (assessed in sixth assessment report (AR6) working group II (WGII)) and biogeochemical cycles. The section also assesses changes in deoxygenation of the oceans due to warming, increased stratification of the surface ocean and slowing of the meridional overturning circulation.

Section 5.4 covers the future projections of biogeochemical cycles and their feedbacks to the climate system fully utilising the database of the concentration-driven coupled model intercomparison project phase 6 (CMIP6). Since AR5, Earth system models (ESMs) have made progress towards including more complex carbon cycle and associated biogeochemical processes that enable exploring a range of possible future carbon-climate feedbacks and their influences on the climate system. The section addresses uncertainties and limits of our models to predict future dynamics for GHG emissions trajectories, as well as new understanding on processes involved in carbon-climate feedbacks and the possibility for rapid and abrupt

ACCEPTED VERSION SUBJECT TO FINAL EDITS

changes brought by non-linear dynamics.

Section 5.5 covers the development of the total and remaining carbon budgets to climate stabilisation targets and the associated transient climate response to cumulative CO_2 emissions. The section shows the progress made since the AR5 (IPCC, 2013a) and the 1.5°C Special Report (IPCC, 2018a), particularly on key components required to estimate the remaining carbon budget, including the transient response to cumulative emissions of CO_2, the zero emission commitment, the projected non-CO_2 warming, and the unrepresented Earth system feedbacks.

Section 5.6 assesses the impacts of carbon dioxide removal and solar radiation modification for the purpose of climate mitigation on the global carbon cycle building from the assessment in the IPCC Special Report on Climate Change and Land (SRCCL). It includes an overview of the major carbon dioxide removal options and potential collateral biogeochemical effects beyond those intended climate mitigation strategies. The potential capacity to deliver atmospheric reductions and the socio-economic feasibility of such options are assessed in detail in AR6 working group III (WGIII).

Finally, Section 5.7 highlights the knowledge gaps as limits to the assessment, which would have strengthened this assessment had those gaps not existed.

Figure 5.1: Visual abstract for Chapter 5.

[END FIGURE 5.1 HERE]

5.1.1 The Physical and Biogeochemical Processes in Carbon-Climate feedbacks

The influence of anthropogenic CO_2 emissions and emission scenarios on the carbon – climate system is primarily driving the ocean and terrestrial sinks as major negative feedbacks (β) that determine the atmospheric CO_2 levels, that then drive climate feedbacks through radiative forcing (γ) (Figure 5.2) (Friedlingstein et al., 2006; Jones et al., 2013b; Jones and Friedlingstein, 2020). Biogeochemical feedbacks follow as an outcome of both carbon and climate forcing on the physics and the biogeochemical processes of the ocean and terrestrial carbon cycles (Figure 5.2) (Katavouta et al., 2018; Williams et al., 2019; Jones and Friedlingstein, 2020). Together, these carbon-climate feedbacks can amplify or suppress climate change by altering the rate at which CO_2 builds up in the atmosphere through changes in the land and ocean sources and sinks (Figure 5.2) (Jones et al., 2013b; Raupach et al., 2014; Williams et al., 2019). These changes depend on the, often non-linear, interaction of the drivers (CO_2 and climate) and processes in the ocean and land as well as the emission scenarios (Figure 5.2; Sections 5.4 and 5.6) (Raupach et al., 2014; Schwinger et al., 2014; Williams et al., 2019). There is *high confidence* that carbon-climate feedbacks and their century scale evolution play a critical role in two linked climate metrics that have significant climate and policy implications: (i) the fraction of anthropogenic CO_2 emissions that remains in the atmosphere, the so-called airborne fraction of CO_2 (AF) (Figure 5.2, Section 5.2.1.2, Figure 5.7, FAQ 5.1), and (ii) the quasi-linear trend characteristic of the transient temperature response to cumulative CO_2 emissions (TCRE) (MacDougall, 2016; Williams et al., 2016; Jones and Friedlingstein, 2020; Section 5.5) and other GHGs (CH_4 and N_2O). This chapter assesses the implications of these issues from a carbon cycle processes perspective (Figure 5.2) in Sections 5.2 (historical and contemporary), 5.3 (changing carbonate chemistry), 5.4 (future projections), 5.5 (remaining carbon budget) and 5.6 (response to carbon dioxide removal and solar radiation modification).

The airborne fraction is an important constraint for adjustments in carbon-climate feedbacks and reflects the partitioning of CO_2 emissions between reservoirs by the negative feedbacks, which for the decade 2010–2019 were 31% on land and 23% in the ocean and also dominated the historical period (Figure 5.2; Table 5.1) (Friedlingstein et al., 2020). During the period 1959–2019, the airborne fraction has largely followed the

ACCEPTED VERSION SUBJECT TO FINAL EDITS

growth in anthropogenic CO_2 emissions with a mean of 44% and a large interannual variability (Ballantyne et al., 2012; Ciais et al., 2019; Friedlingstein et al., 2020) (Section 5.2.1.2; Table 5.1). The negative feedback to CO_2 concentrations is associated with its impact on the air-sea and air-land CO_2 exchange through strengthening of partial pressure of CO_2 (pCO_2) gradients as well as the internal processes that enhance uptake. Two of these key processes are the buffering capacity of the ocean and the CO_2 fertilisation effect on gross primary production (Section 5.4.1–5.4.4).

Positive and negative climate and carbon feedbacks involve, (i) fast processes on land and oceans at time scales from minutes to years such as photosynthesis, soil respiration, net primary production, shallow ocean physics and air-sea fluxes, and (ii) slower processes taking decades to millennia such as changing ocean buffering capacity, ocean ventilation, vegetation dynamics, permafrost changes, peat formation and decomposition (Figure 5.2) (Ciais et al., 2013; Forzieri et al., 2017; Williams et al., 2019). Depending on the particular combination of driver process and response dynamics, they behave as positive or negative feedbacks that amplify or dampen the magnitude and rates of climate change, respectively (Cox et al., 2000; Friedlingstein et al., 2003, 2006; Hauck and Völker, 2015; Williams et al., 2019); red and turquoise arrows in Figure 5.2; Section 5.2.1.5; Table 5.1).

Carbon cycle feedbacks co-exist with climate (heat and moisture) feedbacks (Cross-Chapter Boxes 5.1 and 5.3), which together drive contemporary (Section 5.2) and future (Section 5.4) carbon-climate feedbacks (Williams et al., 2019). The excess heat generated by radiative forcing from increasing concentration of atmospheric CO_2 and other GHGs is mostly taken up by the ocean (> 90%) and the residual balance partitioned between atmospheric, terrestrial and ice melting (Cross-Chapter Box 9.2; Frölicher et al., 2015). The combined effect of these two large scale negative feedbacks of CO_2 and heat are reflected in the TCRE (Section 5.5; Cross-Chapter Box 5.3), which points to a quasi-linear and quasi-emission-path independent relationship between cumulative emissions of CO_2 and global warming, which is used as the basis to estimate the remaining carbon budget (Section 5.5) (MacDougall and Friedlingstein, 2015; MacDougall, 2017; Bronselaer and Zanna, 2020; Jones and Friedlingstein, 2020). There is still *low confidence* on the relative roles and importance of the ocean and terrestrial carbon processes on TCRE variability and uncertainty on centennial time scales (MacDougall, 2016; MacDougall et al., 2017; Williams et al., 2017a; Katavouta et al., 2018, 2019; Jones and Friedlingstein, 2020) (Sections 5.5.1.1, 5.5.1.2).

[START FIGURE 5.2 HERE]

Figure 5.2: Key compartments, processes and pathways that govern historical and future CO_2 concentrations and carbon–climate feedbacks through the coupled earth system. The anthropogenic CO_2 emissions, including land use change, are partitioned via negative feedbacks (turquoise dotted arrows) between the ocean (23%), the land (31%) and the airborne fraction (46%) of anthropogenic CO_2 that sets the changing CO_2 concentration in the atmosphere (2010–2019, Table 5.1). This regulates most of the radiative forcing that creates the heat imbalance that drives the climate feedbacks to the ocean (blue) and land (green). Positive feedbacks (red arrows) result from processes in the ocean and on land (red text). Positive feedbacks are influenced by both carbon-concentration and carbon-climate feedbacks simultaneously. Additional biosphere processes have been included but these have an as yet uncertain feedback impact (blue-dotted arrows). CO_2 removal from the atmosphere into the ocean, land and geological reservoirs, necessary for negative emissions, has been included (grey arrows). Although this schematic is built around CO_2, the dominant GHG, some of the same processes also influence the fluxes of CH_4 and N_2O and the strength of the positive feedbacks from the terrestrial and ocean systems.

[END FIGURE 5.2 HERE]

The combined effects of climate and CO_2 concentration feedbacks on the global carbon cycle are projected by ESMs to modify both the processes and natural reservoirs of carbon on a regional and global scale that may result in positive feedbacks (red arrows in Figure 5.2), which could weaken the major terrestrial and ocean sinks and disrupt both the airborne fraction and TCRE under medium to high emission scenarios (Figure 5.25; Section 5.4.5).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

5.1.2 Paleo Trends and Feedbacks

Paleoclimatic proxy records extend beyond the variability of recent decadal climate oscillations and thus provide an independent perspective on feedbacks between climate and carbon cycle dynamics. These past changes according to reconstructions were slower than the current anthropogenic ones, so they cannot provide an unequivocal comparison. Nonetheless, they can help appraise sensitivities and point toward potentially dominant mechanisms of change (Tierney et al., 2020) on (sub)centennial to (multi)millennial timescales.

AR5 (WGI, Chapter 5) concluded with *medium confidence* that atmospheric CO_2 concentrations reached 350–450 ppm during the mid-Pliocene (3.3–3.0 Ma), and possibly 1000 ppm during the Early Eocene (52–48 Ma). AR5 (WGI, Chapter 5) also concluded with *very high confidence* that the current rates of CO_2, CH_4 and N_2O rise in atmospheric concentrations were unprecedented with respect to the ice core record covering the last deglacial transition (LDT, 18–11 ka) and with *medium confidence* that the rate of change of the reconstructed GHG rise was also unprecedented compared to the lower resolution of the records of the past 800 kyr.

5.1.2.1 Cenozoic Proxy CO_2 Record

Quantifying past changes in the rate of CO_2 accumulation in the atmosphere based on reconstructions using marine sediment proxies is complex as age model uncertainties, assumptions and shortcomings underlying proxy applications and sedimentary processes conspire to alter and confound rate estimates (Ajayi et al., 2020). Indeed, differential sediment mixing and bioturbation contribute to smooth and attenuate proxy records (Hupp and Kelly, 2020), thereby tending to underestimate maximum rates of change (Kemp et al., 2015). Considering the extent to which uncertainties can affect sediment-based rate estimates and notwithstanding recent effort in minimizing their inherent contribution, there is generally *low to medium confidence* in quantifying rates of change on timescale less than a decade back thousands of years, and less than a millennium back millions of years in the past based on marine sediments.

In the past, atmospheric CO_2 concentrations reached much higher levels than present day (see Cross-Chapter Box 2.1; Figure 5.3). In particular, the Paleocene-Eocene thermal maximum (PETM), 55.9–55.7 Ma (Figure 5.3), provides some level of comparison with the current and projected anthropogenic increase in CO_2 emissions (Chapter 2). Atmospheric CO_2 concentrations increased from about 900 to around 2000 ppm in 3–20 kyr as a result of geological carbon release to the ocean-atmosphere system (Zeebe et al., 2016; Gutjahr et al., 2017; Cui and Schubert, 2018; Kirtland Turner, 2018). There is *low to medium confidence* in evaluations of the total amount of carbon released during the PETM, as proxy data constrained estimates vary from around 3000 to more than 7000 PgC, with methane hydrates, volcanic emissions, terrestrial and/or marine organic carbon, or some combination thereof, as the probable sources of carbon (Zeebe et al., 2009; Cui et al., 2011; Gutjahr et al., 2017; Luo et al., 2016; Jones et al., 2019; Elling et al., 2020; Haynes & Hönisch, 2020). Methane emissions related to hydrate/permafrost thawing and fossil carbon oxidation may have acted as positive feedbacks (Lunt et al., 2011; Armstrong McKay and Lenton, 2018; Lyons et al., 2019), as the inferred increase in atmospheric CO_2 can only account for approximately half of the reported warming (Zeebe et al., 2009). The estimated, time-integrated carbon input is broadly similar to the RCP8.5 extension scenario, although CO_2 emission rates (0.3–1.5 Pg yr^{-1}) and by inference the rate of CO_2 accumulation in the atmosphere (4–42 ppm per century) during the PETM were at least 4–5 lower than during the modern era (from 1995 to 2014, Table 2.1) (Zeebe et al., 2016; Gingerich, 2019).

[START FIGURE 5.3 HERE]

Figure 5.3: Atmospheric CO_2 concentrations and growth rates for the past 60 million years and projections to 2100. (a) CO_2 concentrations. Concentrations data for the period 60 Myr to the time prior to 800 Kyr (left

ACCEPTED VERSION SUBJECT TO FINAL EDITS

column) are shown as the LOESS Fit and 68% range (data from Chapter 2) (Foster et al., 2017). Concentrations from 1750 and projections through 2100 are taken from Shared Socioeconomic Pathways of IPCC AR6 (Meinshausen et al., 2017). (b) Growth rates are shown as the time derivative of the concentration time series. Inserts in (b) show growth rates at the scale of the sampling resolution. Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

[END FIGURE 5.1 HERE]

The last 50 Myr have been characterised by a gradual decline in atmospheric CO_2 levels at a rate of ~16 ppm Myr^{-1} (Foster et al., 2017; Gutjahr et al., 2017) (Figure 5.3). The exact cause of this long-term change in CO_2 remains uncertain, but may be related to an imbalance between long-term sources of CO_2 (volcanic outgassing) and long-term sinks (organic carbon burial and silicate weathering).

The most recent time interval when atmospheric CO_2 concentration was as high as 1000 ppm (i.e. similar to the end-of 21st century projection for the high-end emission scenario RCP8.5) was around 33.5 Ma, prior to the Eocene-Oligocene transition (Zhang et al., 2013; Anagnostou et al., 2016). Atmospheric CO_2 levels then reached a critical threshold (1000–750 ppm, (DeConto et al., 2008)) to allow for the development of permanent regional ice-sheets on Antarctica, associated with changes in Southern Ocean hydrography, which would have increased deep ocean CO_2 storage (Leutert et al., 2020).

The most recent interval characterised by atmospheric CO_2 levels similar to modern (i.e. 360–420 ppm) was the Mid-Pliocene warm period (MPWP; 3.3–3.0 Myr, (Martínez-Botí et al., 2015a; de la Vega et al., 2020)) (Chapter 2). The relatively high atmospheric CO_2 concentration during the MPWP are related to vigorous ocean circulation and a rather inefficient marine biological carbon pump (Burls et al., 2017), which would have reduced deep ocean carbon storage. After the MPWP, atmospheric CO_2 concentrations declined gradually at a rate of 30 ppm Myr^{-1} (de la Vega et al., 2020) (Figure 5.3), as an increase in ocean stratification led to enhanced ocean carbon storage, allowing for major, sustained advances in northern hemisphere ice sheets, 2.7 Ma (Sigman et al., 2004; DeConto et al., 2008).

5.1.2.2 Glacial-Interglacial Greenhouse Gases Records

The Antarctic ice core record covering the past 800 kyr provides an important archive to explore the carbon-climate feedbacks prior to anthropogenic perturbations (Brovkin et al., 2016). Polar ice cores represent the only climatic archive from which past GHG concentrations can be directly measured. Major GHGs, CH_4, N_2O and CO_2 generally co-vary on orbital timescales (Loulergue et al., 2008; Lüthi et al., 2008; Schilt et al., 2010) (Chapter 2), with consistently higher atmospheric concentrations during warm intervals of the past, pointing to a strong sensitivity to climate (Figure 5.4). Modelling work suggests that the carbon cycle contributed to globalise and amplify changes in orbital forcing, which are pacing glacial-interglacial climate oscillations (Ganopolski and Brovkin, 2017), with ocean biogeochemistry and physics, terrestrial vegetation, peatland, permafrost and exchanges with the lithosphere including chemical weathering, volcanic activity, sediment burial and marine calcium carbonate compensation all playing a role in modulating the concentration of atmospheric GHGs.

Since AR5, the number of ice core records and the temporal resolution of their data for the last 800 kyr have improved, in particular for the last 60 kyr. Additionally, the advent of isotopic measurements on GHGs extracted from air trapped in ice, allows for more robust source apportionments and inventory assessments. The ensuing discussion will thus mainly focus on these two specific aspects.

Major pre-industrial sources of CH_4 comprise wetlands (including subglacial environments) and biomass burning (Bock et al., 2010, 2017; Lamarche-Gagnon et al., 2019; Kleinen et al., 2020). Pre-industrial atmospheric N_2O concentrations were regulated by microbial production in marine and terrestrial environments and by photochemical removal in the stratosphere (Schilt et al., 2014; Battaglia and Joos, 2018; Fischer et al., 2019). Pre-industrial atmospheric CO_2 concentrations were largely regulated by

ACCEPTED VERSION SUBJECT TO FINAL EDITS

exchange with exogenic terrestrial and ocean carbon reservoirs. The imbalance between geological sources and sinks in the ocean-atmosphere-land biosphere system additionally plays an important role in modulating the air-sea partitioning of the active carbon inventory on multi-millennial timescales (Cartapanis et al., 2018).

[START FIGURE 5.4 HERE]

Figure 5.4: Atmospheric concentrations of CO_2, CH_4 and N_2O in air bubbles and clathrate crystals in ice cores (800,000 BCE to 1990 CE). Note the variable x-axis range and tick mark intervals for the 3 columns. Ice core data is over-plotted by atmospheric observations from 1958 to present for CO_2, from 1984 for CH_4 and from 1994 for N_2O. The time-integrated, millennial-scale linear growth rates for different time periods (800,000–0 BCE, 0–1900 CE and 1900–2017 CE) are given in each panel. For the BCE period, mean rise and fall rates are calculated for the individual slopes between the peaks (interglacials) and troughs (glacial periods), which are given in the panels in left column. The data for BCE period are used from the Vostok, EPICA, Dome C and WAIS ice cores (Petit et al., 1999; Monnin, 2001; Pépin et al., 2001; Raynaud et al., 2005; Siegenthaler et al., 2005; Loulergue et al., 2008; Lüthi et al., 2008; Schilt et al., 2010a). The data after 0–yr CE are taken mainly from Law Dome ice core analysis (MacFarling Meure et al., 2006). The surface observations for all species are taken from NOAA cooperative research network (Dlugokencky and Tans, 2019), where ALT, MLO and SPO stand for Alert (Canada), Mauna Loa Observatory, and South Pole Observatory, respectively. BCE = before current era, CE = current era. Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

[END FIGURE 5.4 HERE]

Model-based estimates indicate that wetland CH_4 emissions were reduced by 24–40% during the Last Glacial Maximum (LGM) when compared to pre-industrial, while CH_4 emissions related to biomass burning (wildfires) decreased by 35–75% (Valdes, et al., 2005; Hopcroft et al., 2017; Kleinen et al., 2020). N_2O emissions decreased by about 30% during the LGM based on data-constrained model estimates (Schilt et al., 2014; Fischer et al., 2019b) owing to a combination of a weaker hydrological cycle and a generally better ventilated intermediate depth ocean relative to present, reducing (de)nitrification processes (Galbraith and Kienast, 2013; Fischer et al., 2019b).

During past ice ages, generally colder and drier climate conditions contributed to a substantial decline of the land biosphere carbon inventory, in particular in boreal peatlands (–300 PgC) (Treat et al., 2019). Estimates assessing the glacial decrease in the global terrestrial biosphere C stock vary between –300 and –600 PgC (Ciais et al., 2012; Peterson et al., 2014; Menviel et al., 2017; Kleinen et al., 2020), possibly –850 PgC when accounting for ocean-sediment interactions and burial (Jeltsch-Thömmes et al., 2019), a considerable contraction when compared to the modern land biosphere stock. The large range of estimates reflects a yet limited understanding on how glacially perturbed nutrient fluxes and soil dynamics, as well as largely exposed shelf areas in the tropics as a result of lowered sea-level, altered carbon cycle dynamics. Recent estimates suggest deep-sea CO_2 storage during the last ice age exceeded modern values by as much as 750 – 950 PgC (Skinner et al., 2015; Buchanan et al., 2016; Skinner et al., 2017; Anderson et al., 2019; Gottschalk et al., 2020). A combination of increased CO_2 solubility associated with 2–3°C lower mean oceanic temperatures (Bereiter et al., 2018), increased oceanic residence time of CO_2 (Skinner et al., 2017), altered oceanic alkalinity (Yu et al., 2010a; Cartapanis et al., 2018), and a generally more efficient marine biological carbon pump (BCP) (Galbraith and Jaccard, 2015; Yu et al., 2019; Galbraith and Skinner, 2020) enhanced the partition CO_2 into the ocean interior, although the relative contribution of each mechanism remains a matter of debate. Recent observationally constrained Earth system model results highlight that air-sea disequilibrium amplifies the effect of cooling and iron fertilisation on glacial carbon storage (Khatiwala et al., 2019).

Ice core observations combined with model-based estimates thus reveal with *high confidence* that both terrestrial and marine CH_4 and N_2O emissions were reduced under glacial climate conditions. Multiple lines of evidence indicate with *high confidence* that enhanced storage of remineralised CO_2 in the ocean interior,

ACCEPTED VERSION SUBJECT TO FINAL EDITS

owing to a combination of synergistic mechanisms, was sufficient to balance the removal of carbon from the atmosphere and the terrestrial biosphere reservoirs combined during the last ice age.

Vegetation regrowth and increased precipitation in wetland regions associated with the mid-deglacial Northern Hemisphere warming (referred to as the Bølling/Allerød (B/A) warm interval, 14.7–12.7 ka), in particular in the (sub)tropics, accounts for large increases in both CH_4 and N_2O emissions to the atmosphere (Schilt et al., 2014; Baumgartner et al., 2014; Bock et al., 2017; Fischer et al., 2019). Specifically, changes in CH_4 sources were steered by variations in vegetation productivity, source size area, temperatures and precipitation as modulated by insolation, local sea-level changes and monsoon intensity (Bock et al., 2017; Kleinen et al., 2020). Changes in the CH_4 atmospheric sink term probably only played a secondary role in modulating atmospheric CH_4 inventories across the LDT (Hopcroft et al., 2017; Kleinen et al., 2020) Geological emissions, related to the destabilisation of fossil (radiocarbon-dead) CH_4 sources buried in continental margins as a result of sudden warming appear small (Bock et al., 2017; Petrenko et al., 2017; Dyonisius et al., 2020). Stable isotope analysis on N_2O extracted from Antarctic and Greenland ice reveal that marine and terrestrial emissions increased by 0.7 ± 0.3 and 1.7 ± 0.3 TgN, respectively, across the LDT (Fischer et al., 2019b). During abrupt Northern Hemisphere warmings, terrestrial emissions responded rapidly to the northward displacement of the Intertropical Convergence Zone (ITCZ) associated with the resumption of the Atlantic meridional overturning circulation (AMOC) (Fischer et al., 2019b). About 90% of these step increases occurred rapidly, possibly in less than 200 years (Fischer et al., 2019b). In contrast, marine emissions increased more gradually, modulated by global ocean circulation reorganisation.

The gradual increase in atmospheric CO_2 across the LDT was punctuated by three centennial 10–13 ppm increments, coeval with 100–200 ppb increases in CH_4 (Marcott et al., 2014), reminiscent of similar oscillations reported for the last ice age associated with transient warming events (Dansgaard/Oeschger (DO) events) (Ahn and Brook, 2014; Rhodes et al., 2017; Bauska et al., 2018) as well as previous deglacial transitions (Nehrbass-Ahles et al., 2020). The rate of change in atmospheric CO_2 accumulation during these transient events exceed the averaged deglacial growth rates by at least 50% (Table 2.1, Figure 5.4). The early deglacial release of remineralised carbon from the ocean abyss coincided with the resumption of Southern Ocean overturning circulation (Skinner et al., 2010; Schmitt et al., 2012; Ferrari et al., 2014; Gottschalk et al., 2016, 2020; Jaccard et al., 2016; Rae et al., 2018; Moy et al., 2019) and the concomitant reduction in the global efficiency of the marine BCP, associated, in part, with dwindling iron fertilisation (Hain et al., 2010; Martinez-Garcia et al., 2014; Jaccard et al., 2016) The two subsequent pulses, centred 14.8 and 12.9 ka, are associated with enhanced air-sea gas exchange in the Southern Ocean (Li et al., 2020a), iron fertilisation in the South Atlantic and North Pacific (Lambert et al., 2021) and rapid increase in soil respiration owing to the resumption of AMOC and associated southward migration of the ITCZ (Bauska et al., 2016; Marcott et al., 2014). Indeed, rapid warming of high northern latitudes contributed to thaw permafrost, possibly liberating labile organic carbon to the atmosphere (Köhler et al., 2014; Crichton et al., 2016; Winterfeld et al., 2018; Meyer et al., 2019). Ocean surface pH reconstructions indicate that the ocean was oversaturated with respect to the atmosphere during the early, mid-LDT (Martínez-Botí et al., 2015b; Shao et al., 2019; Shuttleworth et al., 2021), suggesting that ocean sources may have been larger than terrestrial sources then. Over the course of the LDT, the decrease in northern hemisphere permafrost carbon stocks has been more than compensated by an increase in the carbon stocks of mineral soils, peatland and vegetation (Lindgren et al., 2018; Jeltsch-Thömmes et al., 2019). The land biosphere was on average a net sink for atmospheric carbon and accumulated several hundred Gt of carbon over the LDT.

Detailed investigations reveal that Antarctic air temperatures and more generally Southern Hemisphere (30°S–60°S) proxy temperature reconstructions led the rise in pCO_2 at the onset of the LDT, 18 ka ago, by several hundred years (Shakun et al., 2012; Chowdhry Beeman et al., 2019). Atmospheric CO_2, on the other hand, led reconstructed global average temperature by several centuries (Shakun et al., 2012), corroborating the importance of CO_2 as an amplifier of orbitally-driven warming. The phasing between Antarctic air temperature and atmospheric GHG concentration changes was nearly synchronous, yet variable, during the LDT, owing to the complex nature of the mechanisms modulating the global carbon cycle (Chowdhry Beeman et al., 2019). Mean ocean temperature reconstructions, based on noble gas extracted from Antarctic ice are closely correlated with Antarctic air temperature and pCO_2 records, emphasising the role the Southern Ocean is playing in modulating global climate variability (Bereiter et al., 2018; Baggenstos et al., 2019).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Enhanced mid-ocean ridge magmatism and/or hydrothermal activity modulated by sea-level rise has recently been hypothesised to have contributed to the deglacial CO_2 rise (Crowley et al., 2015; Lund et al., 2016; Huybers and Langmuir, 2017; Stott et al., 2019b). While geological carbon release may have affected the ocean's radiocarbon budget (Ronge et al., 2016; Rafter et al., 2019; Stott et al., 2019a), model results suggest however that the potential contribution of geological carbon sources to the atmosphere remained small (Roth and Joos, 2012; Hasenclever et al., 2017).

Simulations of Earth models of intermediate complexity (EMIC) with coupled glacial-interglacial climate and the carbon cycle were able to reproduce first-order changes in the atmospheric CO_2 content for the first time in recent years (Ganopolski and Brovkin, 2017; Khatiwala et al., 2019). The most important processes accounting for the full deglacial CO_2 amplitude in the models include solubility changes, changes in oceanic circulation and marine carbonate chemistry. The effect of the terrestrial carbon cycle, variable volcanic outgassing and the temperature dependence on the oceanic remineralisation length scale contribute less than 15 ppm CO_2 between the glacial and interglacial intervals of the cycles. However, details in the simulated response of the marine carbon cycle and atmospheric CO_2 concentrations to changes in ocean circulation depend to a large degree on model parametrisation (Gottschalk et al., 2019).

Independent paleoclimatic evidence suggests with *high confidence* that marine and terrestrial CH_4 and N_2O emissions are highly sensitive to climate on (sub)centennial timescales. Limited, yet internally consistent ice core measurements indicate with *medium confidence* that pulsed geologic CH_4 release from continental margins associated with warming remained negligible across the LDT. Multiple lines of evidence suggest with *high confidence* that CO_2 was released from the ocean interior on centennial timescales during the LDT in response to or associated with warming, contributing to the transition out of the last glacial stage to the current interglacial period.

Multiple lines of evidence inferred from marine sediment proxies indicate with *low to medium confidence* that the millennial rates of CO_2 concentration change in the atmosphere during the last 56 Myr were at least 4-5 times lower than during the last century (Figure 5.3). In spite of uncertainties in ice core reconstructions related to delayed enclosure of air bubbles, which tend to smooth the records, there is *high confidence* that the rates of atmospheric CO_2 and CH_4 change during the last century were at least 10 and 5 times faster, respectively, than the maximum centennial growth rate averages of those gases during the last 800 kyr (Fig. 5.4).

5.1.2.3 Holocene Changes

Atmospheric GHG concentrations were much less variable during the pre-industrial Holocene (from 11.7 ka to 1750). Atmospheric CH_4 concentrations decreased at the beginning of the Holocene, consistent with a general weakening of boreal sources (Yang et al., 2017; Beck et al., 2018) and further decline during the Mid-Holocene owing to a reduction in Southern Hemisphere emissions concomitant with a southward shift of the ITCZ (Singarayer et al., 2011; Beck et al., 2018). Atmospheric CH_4 concentrations increased about 5 ka, which prompted the hypothesis of an early anthropogenic influence, related to land use changes in southeast Asia (Ruddiman et al., 2016). However, stable isotope compositions on CH_4 extracted from Greenland and Antarctic ice (Beck et al., 2018) reveal that natural emissions located in the southern tropics were responsible for the rise in atmospheric CH_4 concentrations, in line with model simulations (Singarayer et al., 2011) thus disputing the early anthropogenic influence on the global CH_4 budget. Atmospheric N_2O concentrations increased slightly (20 ppb) across the Holocene, associated with a gradual decline in its nitrogen stable isotope composition (Fischer et al., 2019b). The combined signal is consistent with a small increase in terrestrial emissions, offset by a reduction in marine emissions (Schilt et al., 2010b; Fischer et al., 2019b).

The early Holocene decrease in CO_2 concentration by about 5 ppm (Schmitt et al., 2012) has been attributed to post-glacial regrowth in terrestrial biomass and a gradual increase in peat reservoirs over the Holocene, resulting in the sequestration of several hundred PgC (Yu et al., 2010; Nichols and Peteet, 2019). Peat

ACCEPTED VERSION SUBJECT TO FINAL EDITS

accumulation rates in boreal and temperate regions were higher under warmer summer conditions in the early to middle Holocene (Loisel et al., 2014; Stocker et al., 2017). The 20 ppm gradual increase of atmospheric CO_2 starting 7 ka has been attributed to a decrease in natural terrestrial biomass due to climate change, carbonate compensation and enhanced shallow water carbonate deposition (Menviel and Joos, 2012; Brovkin et al., 2016b), consistent with stable carbon isotope measurements on CO_2 extracted from Antarctic ice (Elsig et al., 2009; Schmitt et al., 2012). These isotopic measurements do not support an early anthropogenic influence on atmospheric CO_2 due to land use change and forest clearing (Ruddiman et al., 2016). Recent paleoceanographic evidence suggests that remineralised carbon outgassing associated with increased Southern Ocean circulation and upwelling (Studer et al., 2018), possibly promoted by stronger Southern Hemisphere westerly winds (Saunders et al., 2018), could have additionally contributed to the late Holocene increase in atmospheric CO_2 concentrations. However, the role of these mechanisms remained insignificant in transient Holocene ESM simulations (Brovkin et al., 2019). Overall, as in AR5 (WGI, Chapter 5), there is *medium confidence* in the key drivers of the CO_2 increase between the early Holocene and the beginning of the industrial era yet there is *low confidence* to the relative contributions of these drivers due to insufficient quantitative constraints on particular processes.

5.2 Historical Trends, Variability and Budgets of CO2, CH4, and N2O

This section assesses the trends and variability in atmospheric accumulation of the three main GHGs (CO_2, CH_4 and N_2O), their ocean and terrestrial sources and sinks as well as their budgets during the Industrial Era (1750–2019). Emphasis is placed on the more recent contemporary period (1959–2019) where understanding is increasingly better constrained by atmospheric, ocean and land observations. The section also assesses our increased understanding of the anthropogenic forcing and processes driving the trends, as well as how variability at the seasonal to decadal scales provide insights on the mechanism governing long-term trends and emerging biogeochemical-climate feedbacks with their regional characteristics.

5.2.1 CO_2: Trends, Variability and Budget

5.2.1.1 Anthropogenic CO_2 Emissions

There are two anthropogenic sources of CO_2: fossil emissions and net emissions (including removals) resulting from land use change and land management (also shown in this chapter as LULUCF: land-use, land-use change, and forestry, termed forestry and other land use (FOLU) in previous IPCC reports). Fossil CO_2 emissions include the combustion of the fossil fuels coal, oil and gas covering all sectors of the economy (electricity, transport, industrial, and buildings), fossil carbonates such as in cement manufacturing, and other industrial processes such as the production of chemicals and fertilisers (Figure 5.5a). Fossil CO_2 emissions are estimated by combining economic activity data and emission factors, with different levels of methodological complexity (tiers) or approaches (e.g., IPCC Guidelines for National Greenhouse Gas Inventories). Several organisations or groups provide estimates of fossil CO_2 emissions, with each dataset having slightly different system boundaries, methods, activity data, and emission factors (Andrew, 2020). Datasets cover different time periods, which can dictate the datasets and methods that are used for a particular application. The data reported here is from an annually updated data source that combines multiple sources to maximise temporal coverage (Friedlingstein et al., 2020). The uncertainty in global fossil CO_2 emissions is estimated to be ±5% (1 standard deviation).

Fossil CO_2 emissions have grown continuously since the beginning of the industrial era (Figure 5.5) with short intermissions due to global economic crises or social instability (Peters et al., 2012; Friedlingstein et al., 2020). In the most recent decade (2010–2019), fossil CO_2 emissions reached an average 9.6 ± 0.5 PgC yr^{-1} and were responsible for 86% of all anthropogenic CO_2 emissions during. In 2019, fossil CO_2 emissions were estimated to be 9.9 ± 0.5 PgC yr^{-1} excluding carbonation (Friedlingstein et al., 2020) the highest on record. These estimates excluding the cement carbonation sink of around 0.2 PgC yr^{-1}. Fossil CO_2 emissions grew at 0.9% yr^{-1} in the 1990s, increasing to 3.0% per year in the 2000s, and reduced to 1.2% from 2010 to

ACCEPTED VERSION SUBJECT TO FINAL EDITS

2019. The slower growth in fossil CO_2 emissions in the last decade is due to a slowdown in growth from coal use. CO_2 emissions from coal use grew at 4.8% yr^{-1} in the 2000s, but they slowed to 0.4% yr^{-1} in the 2010s. CO_2 emissions from oil use grew steadily at 1.1% yr^{-1} in both the 2000s and 2010s. CO_2 emissions from gas use grew at 2.5% yr^{-1} in the 2000s and 2.4% yr^{-1} in 2010s, but is showing signs of accelerated growth of 3% yr^{-1} since 2015 (Peters et al., 2020a). Direct CO_2 emissions from carbonates in cement production are around 4% of total fossil CO_2 emissions, and grew at 5.8% yr^{-1} in the 2000s but a slower 2.4% yr^{-1} in the 2010s. The uptake of CO_2 in cement infrastructure (carbonation) offsets about one half of the carbonate emissions from current cement production (Friedlingstein et al., 2020). These results are robust across the different fossil CO_2 emission datasets, despite minor differences in levels and rates as expected given the reported uncertainties (Andrew, 2020). During 2020, the COVID-19 pandemic led to a rapid, temporary decline in fossil CO_2 emissions, estimated to be around 7% based on a synthesis of four estimates. (Forster et al., 2020; Friedlingstein et al., 2020; Le Quéré et al., 2020; Liu et al., 2020c) (Cross-Chapter Box 6.1).

[START FIGURE 5.5 HERE]

Figure 5.5: Global anthropogenic CO_2 emissions. (a) Historical trends of anthropogenic CO_2 emission (fossil fuels and net land use change, including land management, called LULUCF flux in the main text) for the period 1870 to 2019, with 'others' representing flaring, emissions from carbonates during cement manufacture. Data sources: (Boden et al., 2017; IEA, 2017; Andrew, 2018; BP, 2018; Le Quéré et al., 2018a; Friedlingstein et al., 2020). (b) The net land use change CO_2 flux (PgC yr^{-1}) as estimated by three bookkeeping models and 16 Dynamic Global Vegetation Models (DGVMs) for the global annual carbon budget 2019 (Friedlingstein et al., 2020). The three bookkeeping models are from Hansis et al., (2015); Houghton and Nassikas, (2017); Gasser et al., (2020) and are all updated to 2019; their average is used to determine the net land use change flux in the annual global carbon budget (black line). The DGVM estimates are the result of differencing a simulation with and without land use changes run under observed historical climate and CO_2, following the Trendy v9 protocol; they are used to provide an uncertainty range to the bookkeeping estimates (Friedlingstein et al., 2020). All estimates are unsmoothed annual data. Estimates differ in process comprehensiveness of the models and in definition of flux components included in the net land use change flux. Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

[END FIGURE 5.5 HERE]

The global net flux from land use change and land management is composed of carbon fluxes from land use conversions, land management and changes therein (Pongratz et al., 2018) and is equivalent to the LULUCF fluxes from the agriculture, forestry and other land use (AFOLU) sector (Jia et al., 2019). It thus consists of gross emissions (loss of biomass and soil carbon in clearing or logging, harvested product decay, emissions from peat drainage and burning, degradation) and gross removals (CO_2 uptake in natural vegetation re-growing after harvesting or agricultural abandonment, afforestation). The LULUCF flux relates to direct human interference with terrestrial vegetation, as opposed to the natural carbon fluxes occurring due to interannual variability or trends in environmental conditions (in particular climate, CO_2, and nutrient deposition) (Houghton, 2013).

Progress since AR5 and the SRCCL (IPCC, 2019a) allows more accurate estimates of gross and net fluxes due to availability of more models, model advancement in terms of inclusiveness of land-use practices (see below), and advanced land use forcings (Ciais et al., 2013; Goldewijk et al., 2017; Hurtt et al., 2020). In addition, important terminological discrepancies were resolved. First, synergistic effects of land use change and environmental changes-have been identified as a key reason for the large discrepancies between model estimates of the LULUCF flux, explaining up to 50% of differences (Pongratz et al., 2014; Stocker and Joos, 2015; Gasser et al. 2020). Another reason for discrepancies relates to natural fluxes being considered as part of the LULUCF flux when occurring on managed land in the United Nation Framework Convention on Climate Change (UNFCCC) national greenhouse gas inventories; these fluxes are considered part of the natural terrestrial sink in global vegetation models and excluded in bookkeeping models (Grassi et al., 2018). LULUCF fluxes following national GHG inventories or FAO datasets, including recent estimates (Tubiello

ACCEPTED VERSION SUBJECT TO FINAL EDITS

et al., 2021), are thus excluded from our global assessment, but their comparison against the academic approach is available elsewhere (at the global scale (Jia et al., 2019) and European level (Petrescu et al., 2020).

Land-use-related component fluxes can be verified by the growing databases of global satellite-based biomass observations in combination with information on remotely-sensed land cover change, but differ from bookkeeping and modelling with Dynamic Global Vegetation Models (DGVMs) in excluding legacy emissions from pre-satellite-era land use change and land management, and neglecting soil carbon changes, and often focus on gross deforestation, not regrowth (Jia et al., 2019).

For the decade 2010–2019, average emissions were estimated at 1.6 ± 0.7 PgC yr^{-1} (mean ± standard deviation, 1 sigma) (Friedlingstein et al., 2020). A *likely* general upward trend since 1850 is reversed during the second part of the 20th century (Figure 5.5b). Trends since the 1980s have *low confidence* because they differ between estimates, which is related inter alia to Houghton and Nassikas (2017) using a different land use forcing than Hansis et al. (2015) and the DGVMs. Higher emissions estimates are expected from DGVMs run under transient environmental conditions compared to bookkeeping estimates, because the DGVM estimate includes the loss of additional sink capacity. Because the transient setup requires a reference simulation without land use change to separate anthropogenic fluxes from natural land fluxes, LULUCF estimates by DGVMs include the sink forests would have developed in response to environmental changes on areas that in reality have been cleared (Pongratz et al., 2014). The agricultural areas that replaced these forests have a reduced residence time of carbon, lacking woody material, and thus provide a substantially smaller additional sink over time (Gitz and Ciais, 2003). The loss of additional sink capacity is growing in particular with atmospheric CO_2 and increases DGVM-based LULUCF flux estimates relative to bookkeeping estimates over time (Figure 5.5).

Gross emissions are on average 2–3 times larger than the net flux from LULUCF, increasing from an average of 3.5 ± 1.2 PgC yr^{-1} for the decade of the 1960s to an average of 4.4 ± 1.6 PgC yr^{-1} during 2010–2019 (Friedlingstein et al., 2020). Gross removals partly balance these gross emissions to yield as the sum the net flux from LULUCF and increase from -2.0 ± 0.7 PgC yr^{-1} for the 1960s to -2.9 ± 1.2 PgC yr^{-1} during 2010-2019. These large gross fluxes show the relevance of land management such as harvesting or rotational agriculture and the large potential to reduce emissions by halting deforestation and degradation.

More evidence on the pre-industrial LULUCF flux has emerged since AR5 in the form of new estimates of cumulative carbon losses until today and of a better understanding of natural carbon cycle processes over the Holocene (Ciais et al., 2013). Cumulative carbon losses by land use activities since the start of agriculture and forestry (pre-industrial and industrial era) have been estimated at 116 PgC based on global compilations of carbon stocks for soils (Sanderman et al., 2017) with about 70 PgC of this occurring prior to 1750, and for vegetation as 447 PgC (inner quartiles of 42 calculations: 375–525 PgC) (Erb et al., 2018). Emissions prior to 1750 can be estimated by subtracting the post-1750 LULUCF flux from Table 5.1 from the combined soil and vegetation losses until today; they would then amount to 328 (161–501) PgC assuming error ranges are independent. A share of 353 (310–395) PgC from prior to 1800 has indirectly been suggested as the difference between net biosphere flux and terrestrial sink estimates, which is compatible with ice-core records due to a low airborne fraction of anthropogenic emissions in pre-industrial times (Erb et al., 2018) (see also Section 5.1.2.3). *Low confidence* is assigned to pre-industrial emissions estimates.

Since AR5, evidence emerged that the LULUCF flux might have been underestimated as DGVMs include anthropogenic land cover change, but often ignore land management practices not associated with a change in land cover; land management is more widely captured by bookkeeping models through use of observation-based carbon densities (Ciais et al., 2013; Pongratz et al., 2018). Sensitivity studies show that practices such as wood and crop harvesting increase global net LULUCF emissions (Arneth et al., 2017) and explain about half of the cumulative loss in biomass (Erb et al., 2018).

5.2.1.2 Atmosphere

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Atmospheric CO_2 concentration measurements in remote locations began in 1957 at the South Pole Observatory (SPO) and in 1958 at Mauna Loa Observatory (MLO), Hawaii, USA (Keeling, 1960) (Figure 5.6a). Since then, measurements have been extended to multiple locations around the world (Bacastow et al., 1980; Conway et al., 1994; Nakazawa et al., 1997). In addition, high density global observations of total column CO_2 measurements have been made since 2009 by dedicated greenhouse gases observing satellites (Yoshida et al., 2013; O'Dell et al., 2018). Annual mean CO_2 growth rates are observed to be 1.56 ± 0.18 ppm yr^{-1} (average and range from 1 standard deviation of annual values) over the 61 years of atmospheric measurements (1959–2019), with the rate of CO_2 accumulation almost tripling from an average of 0.82 ± 0.29 ppm yr^{-1} during the decade of 1960–1969 to 2.39 ± 0.37 ppm yr^{-1} during the decade of 2010–2019 (Chapter 2). The latter agrees well with that derived for total column (XCO_2) measurements by the greenhouse gases observing satellite (GOSAT) (Figure 5.6b). The interannual oscillations in monthly-mean CO_2 growth rates (Figure 5.6b) show close relationship with the El Niño southern oscillation (ENSO) cycle (Figure 5.6b) due to the ENSO-driven changes in terrestrial and ocean CO_2 sources and sinks on the Earth's surface (Section 5.2.1.4).

Multiple lines of evidence unequivocally establish the dominant role of human activities in the growth of atmospheric CO_2. First, the systematic increase in the difference between the MLO and SPO records (Figure 5.6a) is caused primarily by the increase in emissions from fossil fuel combustion in industrialised regions that are situated predominantly in the northern hemisphere (Ciais et al., 2019). Second, measurements of the stable carbon isotope in the atmosphere ($\delta^{13}C–CO_2$) are more negative over time because CO_2 from fossil fuels extracted from geological storage is depleted in ^{13}C (Rubino et al., 2013; Keeling et al., 2017) (Figure 5.6c). Third, measurements of the $\delta(O_2/N_2)$ ratio show a declining trend because for every molecule of carbon burned, 1.17 to 1.98 molecules of oxygen (O_2) is consumed (Ishidoya et al., 2012; Keeling and Manning, 2014) (Figure 5.6d). These three lines of evidence confirm unambiguously that the atmospheric increase of CO_2 is due to an oxidative process (i.e. combustion). Fourth, measurements of radiocarbon ($^{14}C–CO_2$) at sites around the world (Levin et al., 2010; Graven et al., 2017; Turnbull et al., 2017) show a continued long-term decrease in the $^{14}C/^{12}C$ ratio. Fossil fuels are devoid of ^{14}C and therefore fossil-fuel-derived CO_2 additions decrease the atmospheric $^{14}C/^{12}C$ ratio (Suess, 1955).

[START FIGURE 5.6 HERE]

Figure 5.6: Time series of CO_2 concentrations and related measurements in ambient air. (a) concentration time series and MLO-SPO difference, (b) growth rates, (c) ^{14}C and ^{13}C isotopes, and (d) O_2/N_2 ratio. The data for Mauna Loa Observatory (MLO) and South Pole Observatory (SPO) are taken from the Scripps Institution of Oceanography (SIO)/University of California, San Diego (Keeling et al., 2001). The global mean CO_2 are taken from NOAA cooperative network (as in Chapter 2), and GOSAT monthly-mean XCO_2 time series are taken from National Institute for Environmental Studies (Yoshida et al., 2013). CO_2 growth rates are calculated as the time derivative of deseasonalised time series (Nakazawa et al., 1997). The $\Delta(O_2/N2)$ are expressed in per meg units (= $(FF/M)\times10^6$, where FF = moles of O_2 consumed by fossil-fuel burning, M = 3.706×10^{19}, total number of O_2 molecules in the atmosphere (Keeling and Manning, 2014). The $^{14}CO_2$ time series at Barring Head, Wellington, New Zealand (BHD) is taken from GNS Science and NIWA (Turnbull et al., 2017). The multivariate ENSO index (MEI) is shown as the shaded background in panel (b; warmer shade indicates El Niño). Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

[END FIGURE 5.6 HERE]

Over the past six decades, the fraction of anthropogenic CO_2 emissions that has accumulated in the atmosphere (referred to as airborne fraction) has remained near constant at approximately 44% (Figure 5.7) (Ballantyne et al., 2012; Ciais et al., 2019; Gruber et al., 2019b; Friedlingstein et al., 2020). This suggests that the land and ocean CO_2 sinks have continued to grow at a rate consistent with the growth rate of anthropogenic CO_2 emissions, albeit with large inter-annual and sub-decadal variability dominated by the land sinks (Figure 5.7).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Since AR5, an alternative observable diagnostic to the airborne fraction has been proposed to understand the trends in land and ocean sinks in response to its driving atmospheric CO_2 concentrations (Raupach et al., 2014; Bennedsen et al., 2019). It is the sink rate which is defined as the combined ocean and land sink flux per unit of atmospheric excess of CO_2 above pre-industrial levels (Raupach et al., 2014). The sink rate has declined over the past six decades, which indicates that the combined ocean and land sinks are not growing as fast as the growth in atmospheric CO_2 (Raupach et al., 2014; Bennedsen et al., 2019). Possible explanations for the sink rate decline are that the land and/or ocean CO_2 sinks are no longer responding linearly with CO_2 concentrations or that anthropogenic emissions are slower than exponential (Gloor et al., 2010; Raupach et al., 2014; Bennedsen et al., 2019) (Figure 5.7; Sections 5.2.1.3, 5.2.1.4). In addition, both diagnostics are influenced by major climate modes (e.g. ENSO) and volcanic eruptions that contribute to high interannual variability (Gloor et al., 2010; Frölicher et al., 2013; Raupach et al., 2014), suggesting high sensitivity to future climate change. Uncertain land use change fluxes (Section 5.2.1.2) influence the robustness of the trends. Based on the AF, it is concluded with *medium confidence* that both ocean and land CO_2 sinks have grown consistent with the rising of anthropogenic emissions. Further research is needed to understand the drivers of changes in the CO_2 sink rate.

[START FIGURE 5.7 HERE]

Figure 5.7: Airborne fraction and anthropogenic (fossil fuel and land use change) CO_2 emissions. Data as in Section 5.2.1.1. The multivariate ENSO index (shaded) and the major volcanic eruptions are marked along the x-axis. Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

[END FIGURE 5.7 HERE]

5.2.1.3 Ocean Carbon Fluxes and Storage

Since AR5 and the Special Report on Ocean and the Cryosphere (SROCC), major advances in globally coordinated ocean CO_2 observations (Surface Ocean CO_2 Atlas - SOCAT and Global Ocean Data Analysis Project - GLODAP), the harmonisation of ocean and coastal observations based products, atmospheric and oceanic inversion models and forced global ocean biogeochemical models (GOBMs) have increased the level of confidence in the assessment of trends and variability of air-sea fluxes and storage of CO_2 in the ocean during the historical period (1960–2018) (Ciais et al., 2013; Bakker et al., 2016; Landschützer et al., 2020, 2016; Bindoff et al., 2019; Tohjima et al., 2019; DeVries et al., 2019; Gregor et al., 2019; Gruber et al., 2019c, 2019a; Olsen et al., 2020; Friedlingstein et al., 2020; Hauck et al., 2020) (See also Supplementary Materials 5.SM.1). A major advance since SROCC is that for the first time all 6 published observational product fluxes, used in this assessment, are made more comparable using a common ocean and sea-ice cover area, integration of climatological coastal fluxes scaled to increasing atmospheric CO_2 and an ensemble mean of ocean fluxes calculated from three re-analysis wind products (Landschützer et al., 2014, 2020; Rödenbeck et al., 2014; Zeng et al., 2014; Denvil-Sommer et al., 2019; Gregor et al., 2019; Iida et al., 2020) Supplementary Materials 5.SM.2). From a process point of view, the ocean uptake of anthropogenic carbon is a two-step set of abiotic processes that involves the exchange of CO_2, first across the air-sea boundary into the surface mixed layer, followed by its transport into the ocean interior where it is stored for decades to millennia, depending on the depth of storage (Gruber et al., 2019a), Two definitions of air-sea fluxes of CO_2 are used in this assessment for both observational products and models: S_{ocean} is the global mean ocean CO_2 sink and F_{net} denotes the net spatially varying CO_2 fluxes (Hauck et al., 2020). Adjustment of the mean global F_{net} for the pre-industrial sea-to-air CO_2 flux associated with land-to-ocean carbon flux term makes F_{net} comparable to S_{ocean} (Jacobson et al., 2007; Resplandy et al., 2018a; Hauck et al., 2020).

There are multiple lines of observational and modelling evidence that support with *high confidence* the finding that in the historical period air-sea fluxes and storage of anthropogenic CO_2 are largely influenced by atmospheric CO_2 concentrations, physical ocean processes and physico-chemical carbonate chemistry, which determines the unique properties of CO_2 in sea water (Wanninkhof et al., 2014; DeVries et al., 2017; Gruber

ACCEPTED VERSION SUBJECT TO FINAL EDITS

et al., 2019, 2019a; Hauck et al., 2020; McKinley et al., 2017; 2020; Chapter 9, Cross-Chapter Box 5.3). Here we assess three different approaches (Figures 5.8a, 5.8b and 5.9) that together provide *high confidence* that during the historical period (1960–2018) the ocean carbon sink (S_{ocean}) and its associated ocean carbon storage have grown in response to global anthropogenic CO_2 emissions (Gruber et al., 2019c; Hauck et al., 2020; McKinley et al., 2020).

5.2.1.3.1 Ocean Carbon Fluxes and Storage: Global Multi-Decadal Trends

In the first assessment approach, the mean global multidecadal (1960–2019) trends in the ocean sink (S_{ocean}) for CO_2 show a high degree of coherence across the 9 GOBMs and 6 pCO_2-based observational product reconstructions (1987–2018), which despite a temporary slowdown (or "hiatus") in the 1990s, is also quasi-linear over that period (Figure 5.8a) (Gregor et al., 2019; Hauck et al., 2020). This coherence between the GOBMs and observations-based reconstructions (1987–2018; r^2=0.85) provides *high confidence* that the ocean sink (S_{ocean} in Section 5.2.1.5) evaluated from GOBMs (1960–2019) grew quasi-linearly from 1.0 ± 0.3 PgC yr^{-1} to 2.5 ± 0.6 PgC yr^{-1} between the decades 1960–1969 and 2010–2019 in response to global CO_2 emissions (Figure 5.8a; Table 5.1; Hauck et al., 2020; Friedlingstein et al., 2020). The cumulative ocean CO_2 uptake (105 ± 20 PgC) is 23% of total anthropogenic CO_2 emissions (450 ± 50 PgC) for the same period (Friedlingstein et al., 2020). Notwithstanding the *high confidence* in the magnitude of the annual to decadal trends for S_{ocean} this assessment is moderated to *medium confidence* by the *low confidence* in the currently inadequately constrained uncertainties in the pre-industrial land-to-ocean carbon flux, the uncertain magnitude of winter outgassing from the Southern Ocean, and the uncertain effect of the ocean surface cool-skin, the effect of data sparsity, differences between wind products and the uncertain contribution from the changing land-ocean continuum on global and regional fluxes (Jacobson et al., 2007; Resplandy et al., 2018a; Roobaert et al., 2018; Bushinsky et al., 2019; Gloege et al., 2020; Hauck et al., 2020; Watson et al., 2020). However, both GOBMs and pCO_2-based observational products independently reveal a slowdown or "hiatus" of the ocean sink in the 1990s, which provides a valuable constraint for model verification and leads to greater confidence in the model outputs (Figure 5.8a) (Landschützer et al., 2016; Gregor et al., 2018; DeVries et al., 2019; Hauck et al., 2020). A number of studies point to the role of the Southern Ocean in the global "1990s-hiatus" in air-sea CO_2 fluxes but provide different process-based explanations linking ocean temperature, mixing and MOC responses to variability in large scale climate systems, wind stress and volcanic activity as well as the sensitivity of the air-sea CO_2 flux to small changes in the atmospheric forcing from anthropogenic CO_2 (Landschützer et al., 2016; DeVries et al., 2017; Bronselaer et al., 2018; Gregor et al., 2018; Gruber et al., 2019c; Keppler and Landschützer, 2019; McKinley et al., 2020; Nevison et al., 2020). Data sparsity in the Southern Ocean could also be a factor amplifying the global decadal perturbation of the 1990s (Gloege et al., 2020). Therefore, while there is *high confidence* in the 1990's-hiatus of the global ocean sink for anthropogenic CO_2 and that the Southern Ocean makes an observable contribution to it, there is still *low confidence* in the attribution for the processes behind the 1990s-hiatus (5.2.1.3.2). Observed increases in the amplitude of the seasonal cycle of ocean pCO_2 and reductions in the mean global buffering capacity provide *high confidence* that growing CO_2 sink is also beginning to drive observable large-scale changes in ocean carbonate chemistry (Jiang et al., 2019). However, there is *medium confidence* that these changes, which depending on the emissions scenario could drive future ocean feedbacks, are still too small to emerge from the historical multi-decadal observed growth rate of S_{ocean} (Figure 5.8a; Sections 5.1.2; 5.3.2, 5.4.2; SROCC 5.2.2.3.2) (Bates et al., 2014; Sutton et al., 2016; Fassbender et al., 2017; Landschützer et al., 2018; Jiang et al., 2019). A recent model-based study suggests that re-emergence of previously stored anthropogenic CO_2 is both changing the buffering capacity of the mixed layer and reducing the ocean sink for anthropogenic CO_2 during the historical period (Rodgers et al., 2020). This trend is not reflected in observations-based products (Figure 5.8), so we attribute a *low confidence*.

The second assessment approach makes use of 6 independent methods to constrain the mean decadal ocean sink over the period 1990–2019 (Figure 5.8b). This provides a multi-decadal advance on the 1990–1999 decadal constraint from (Denman et al., 2007) that have been widely used as a model constraint for GOBMs used for the global carbon budget (Hauck et al., 2020). The *medium confidence* attributed of this assessment of the global multi-decadal trend (Figure 5.8a) is further supported by the broad agreement in magnitude and trend of the decadal mean ocean CO_2 uptake with assessments that also include additional observations-based, independent methods such as ocean CO_2 inversion and atmospheric CO_2 and O_2/N_2 measurements

ACCEPTED VERSION SUBJECT TO FINAL EDITS

(Figure 5.8b; Supplementary Materials Tables 5.SM.1 and 5.SM.2).

[START FIGURE 5.8 HERE]

Figure 5.8: Multi-decadal trends for the ocean sink of CO_2. (a): The multi-decadal (1960–2019) trends in the annual ocean sink (S_{ocean}) reconstructed from 9 Global Ocean Biogeochemical Models (GOBM) forced with observed atmospheric re-analysis products (Hauck et al., 2020), 6 observationally-based gap-filling products that reconstructed spatial and temporal variability in the ocean CO_2 flux from sparse observations of surface ocean pCO_2 (Supplementary Materials 5.SM.2). The trends in S_{ocean} were calculated from the mean annual global GOBM outputs and the observational products were used to provide confidence in the GOBM assessments (r^2=0.85). Thick lines represent the multi-model mean. Observationally-based products have been corrected for pre-industrial river carbon fluxes (0.62 PgC yr^{-1}) based on the average of estimates from Jacobson et al., (2007) and Resplandy et al. (2018). (b): Mean decadal constraints and their confidence intervals for global ocean sink (S_{ocean}) of anthropogenic CO_2 using multiple independent or quasi-independent lines of evidence or methods for the period 1990–2019 (See Supplementary Materials Tables 5.SM.1 and 5.SM.2 for magnitudes, uncertainties and published sources). Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

[END FIGURE 5.8 HERE]

Here we provide a third comparative assessment approach depicting the spatial coherence of ocean air-sea fluxes and storage rates of CO_2 as well as a quantitative assessment of both fluxes for the same period (1994–2007) (Figure 5.9). Observation-based pCO_2 flux products show that emissions of natural CO_2 occur mostly in the tropics and high latitude Southern Ocean, and that the uptake and storage of anthropogenic CO_2 occur predominantly in the mid-latitudes (Figure 5.9; Chapter 9; Cross-Chapter Box 5.3). Strong ocean CO_2 sink regions are those in the mid-latitudes associated with the cooling of poleward flowing sub-tropical surface waters as well as equatorward flowing sub-polar surface waters both of which contribute to the formation of Mode, Intermediate and Deep water masses that transport anthropogenic CO_2 into the ocean interior on time scales of decades to centuries in both hemispheres (Figure 5.9) (DeVries, 2014; Gruber et al., 2019a; Wu et al., 2020; Chapter 9.2.2.3). The mean decadal scale magnitude and uncertainties of S_{ocean} from net air sea fluxes (F_{net}) were calculated from an ensemble of 6 observational based product reconstructions (Figure 5.9a) and the storage rates in the ocean interior derived from multiple ocean interior CO_2 data sets (Gruber et al., 2019a) (Figure 5.9b). The cumulative CO_2 stored in the ocean interior from 1800 to 2007 has been estimated at 140 ±18 PgC (Gruber et al., 2019a). As reported in SROCC (Section 5.2.2.3.1; IPCC, 2019b), the net ocean CO_2 storage between 1994–2007 was 29 ± 4 PgC, which corresponds to a mean storage of 26 ± 5% of anthropogenic CO_2 emissions for that period (Gruber et al., 2019a). The resulting net annual storage rate of anthropogenic CO_2, equivalent to S_{ocean} for the period mid-1994–mid-2007 is 2.2 ± 0.3 $PgCyr^{-1}$, which is in very close agreement with the top-down air-sea flux estimate of S_{ocean} of 2.1 ± 0.5 PgC yr^{-1} from GOBMs and 1.9 ± 0.3PgC yr^{-1} from pCO_2-based observational products with the steady river carbon flux correction of 0.62PgCy-1 for the same time period (Gruber et al., 2019b; Hauck et al., 2020). This close agreement between these independent ocean CO_2 sink estimates derived from air-sea fluxes and storage rates in the ocean interior support the *medium confidence* assessment that the ocean anthropogenic carbon storage rates continue to be determined by the ocean sink (S_{ocean}) in response to growing CO_2 emissions (McKinley et al., 2020) (Figure 5.9).

[START FIGURE 5.9 HERE]

Figure 5.9: Comparative regional characteristics of the mean decadal (1994–2007) sea-air CO_2 flux (F_{net}) and ocean storage of anthropogenic CO_2. (a) regional sink–source characteristics for contemporary ocean air-sea CO_2 fluxes (F_{net}) derived from the ensemble of 6 observation-based products using SOCATv6 observational data set (Bakker et al., 2020; Landschützer et al., 2014; Rödenbeck et al., 2014; Zeng et al., 2014; Denvil-Sommer et al., 2019; Gregor et al., 2019; Iida et al., 2020). Warm colours depict outgassing fluxes and black contours characterise the the five basin-scale biomes aggregated from the original 17

ACCEPTED VERSION SUBJECT TO FINAL EDITS

from Fay and McKinley (2014) and adjusted by Gregor et al., (2019) also used to calculate the regional variability in flux anomalies (Supplementary Materials Figure 5.SM.1); and (b) the regional characteristics of the storage fluxes of CO_2 in the ocean interior for the same period (Gruber et al., 2019a). The dots reflect ocean areas where the 1-sigma standard deviation of Fnet from the 6 observation product is larger than the magnitude of the mean. This reflects source-sink transition areas where the mean Fnet is small and more strongly influenced by spatial and temporal variability across the products. Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

[END FIGURE 5.9 HERE]

5.2.1.3.2 Ocean Carbon Fluxes and Storage: Regional – Global Variability

The intent of this assessment is to show how global variability can be regionally forced (Gregor et al., 2019; Landschützer et al., 2019; Hauck et al., 2020). Since AR5 and SROCC, advances in global ocean CO_2 flux products, GOBMs and atmospheric inversion models have strengthened the confidence in the assessment of how ocean regions influence mean global variability and trends of ocean CO_2 air-sea fluxes (F_{net}; see Supplementary Materials Figure 5.SM.1) (Ciais et al., 2013; Landschützer et al., 2014, 2015; Rödenbeck et al., 2014; McKinley et al., 2017; Bindoff et al., 2019; Gregor et al., 2019; Friedlingstein et al., 2020; Hauck et al., 2020). The coherence in the regional variability of the anomalies in F_{net} from 3 independent lines of evidence support with *high confidence* that the non-steady state global interannual-decadal variability of F_{net} has clear regional influences (Gregor et al., 2019; Landschützer et al., 2019). The tropical oceans contribute the most to the global mean interannual variability (Supplementary Materials Figure 5.SM.1d). The high latitude oceans, particularly the Southern Ocean, contribute the most to the global-scale decadal variability (Supplementary Materials Figure 5.SM5.1b, c; (Landschützer et al., 2016, 2019; Gregor et al., 2019; Gruber et al., 2019c; Hauck et al., 2020). The influence of the Southern Ocean on the global mean decadal variability and the 1990's hiatus is supported by the highest regional-global correlation coefficients (Supplementary Materials Figures 5.SM.1a, c). In contrast, the Equatorial oceans' influence on global mean F_{net} has a low correlation because, notwithstanding the coherence in interannual variability, it does not show the same global mean trend of strengthening sink in response to growing global emissions (Supplementary Materials Figure 5.SM.1d; (Gregor et al., 2019). All regions, except the Equatorial ocean, contribute to varying extents to the multidecadal trend of growth in the global ocean sink (Supplementary Materials Figure 5.SM.1). Data sparseness in the high latitudes and the relatively short length of the observational records leads to *low confidence* in the attribution of the processes that link regional-global variability to climate (Landschützer et al., 2019; Gloege et al., 2020).

Regional decadal-scale anomalies in the variability of ocean CO_2 storage have also emerged, probably associated with changes in the meridional overturning circulation (MOC), which may influence the global variability in F_{net} (DeVries et al., 2017); Chapter 9). In the interior of the Indian and Pacific sectors of the Southern Ocean, and the North Atlantic, the increase in the CO_2 inventory from 1994 to 2007 was about 20% smaller than expected from the atmospheric CO_2 increase during the same period and the anthropogenic CO_2 inventory in 1994 (Sabine, 2004; Gruber et al., 2019a). There is *medium confidence* that the ocean CO_2 inventory strengthened again in the decade 2005–2015 (DeVries et al., 2017). In the North Atlantic, a low rate of anthropogenic CO_2 storage at 1.9 ± 0.4 PgC per decade during the time period of 1989–2003 increased to 4.4 ± 0.9 PgC per decade during 2003–2014, associated with changing ventilation patterns driven by the North Atlantic Oscillation (Woosley et al., 2016). In the Pacific sector of the Southern Ocean, the rate of anthropogenic CO_2 storage also increased from 8.8 ± 1.1 (1σ) PgC per decade during 1995–2005 to 11.7 ± 1.1 PgC per decade during 2005–2015 (Carter et al., 2019). However, in the Subantarctic Mode Water of the Atlantic sector of the Southern Ocean, the storage rate of the anthropogenic CO_2 was rather lower after 2005 than before (Tanhua et al., 2017; Bindoff et al., 2019; Section 9.2.3.2). These changes have been predominantly ascribed to the impact of changes in the MOC on the transport of anthropogenic CO_2 into the ocean interior due to regional climate variability, in addition to the increase in the atmospheric CO_2 concentration (Wanninkhof et al., 2010; Pérez et al., 2013; DeVries et al., 2017, 2019; Gruber et al., 2019b; McKinley et al., 2020) (Section 9.2.3.1). However, the low frequency of carbon observations in the interior of the vast ocean leads to *medium confidence* in the assessment of temporal variability in the rate of regional ocean CO_2 storage and its controlling mechanisms.

ACCEPTED VERSION SUBJECT TO FINAL EDITS

In summary, multiple lines of both observational and modelling evidence provide *high confidence* that the finding that the ocean sink for anthropogenic CO_2 has increased quasi-linearly over the past 60 years in response to growing global emissions of anthropogenic CO_2 with a mean fraction of 23% of total emissions. The *high confidence* assessment is moderated to *medium confidence* because of a number of as yet to be adequately unconstrained ocean CO_2 flux terms. Observed changes in the variability of ocean pCO_2 and observed reductions in the mean global buffering capacity provide *high confidence* that the growing CO_2 sink is also beginning to drive observable large-scale changes in ocean carbonate chemistry. However, there is *medium confidence* that these changes, which depending on the emissions scenario could drive future ocean feedbacks, are still too small to emerge from the historical multi-decadal observed growth rate of S_{ocean}.

5.2.1.4 Land CO_2 Fluxes: Historical and Contemporary Variability and Trends

5.2.1.4.1 Trend in Land-Atmosphere CO2 Exchange

The global net land CO_2 sink is assessed to have grown over the past six decades (Ciais et al., 2019; Le Quéré et al., 2018a; Sarmiento et al., 2010; Friedlingstein et al., 2019) (*high confidence*). Estimated as the residual from the mass balance budget of fossil fuel CO_2 emissions minus atmospheric CO_2 growth and the ocean CO_2 sink, the global net land CO_2 sink (including both land CO_2 sink and net land use change emission) increased from 0.3 ± 0.6 PgC yr^{-1} during the 1960s to 1.8 ± 0.8 PgC yr^{-1} during 2010s (Friedlingstein et al., 2020). An increasing global net land CO_2 sink since 1980s (Figure 5.10) was consistently suggested both by atmospheric inversions (e.g. Peylin et al., 2013) and by Dynamic Global Vegetation Models (e.g. Sitch et al., 2015; Friedlingstein et al., 2019). The northern hemisphere contributes more to the net increase in the land CO_2 sink compared to the southern hemisphere (Ciais et al., 2019), and boreal and temperate forests probably contribute the most (Tagesson et al., 2020). Attributing an increased net land CO_2 sink to finer regional scales remains challenging, but inversions of satellite-based column CO_2 products that have emerged since AR5 are a promising tool to further constrain regional land-atmosphere CO_2 exchange (Ciais et al., 2013; Houweling et al., 2015; Reuter et al., 2017; O'Dell et al., 2018; Palmer et al., 2019a).

Carbon uptake by vegetation photosynthesis exerts a first-order control over the net land CO_2 sink. Several lines of evidence show enhanced vegetation photosynthesis over the past decades (*medium to high confidence*) (Figure 5.10), including increasing satellite-derived vegetation greenness (e.g. Mao et al., 2016; Zhu et al., 2016; Jia et al., 2019; See also Chapter 2) and satellite-derived photosynthesis indicators (e.g. Badgley et al., 2017; Zhang et al., 2018b), change in atmospheric concentration of carbonyl sulphide (Campbell et al., 2017), enhanced seasonal CO_2 amplitude (Graven et al., 2013; Forkel et al., 2016). observation-driven inference of increasing photosynthesis CO_2 uptake based mostly on enhanced water use efficiency (Cheng et al., 2017), and DGVM simulated increase of photosynthesis CO_2 uptake (Anav et al., 2015).

Substantial progress has been made since AR5 on attributing change of the global net land CO_2 sink. Increasing global net land CO_2 sink since the 1980s is mainly driven by the fertilisation effect from rising atmospheric CO_2 concentrations (Schimel et al., 2015; Sitch et al., 2015; Fernández-Martínez et al., 2019; O'Sullivan et al., 2019; Tagesson et al., 2020; Walker et al., 2020) (*medium confidence*). Increasing nitrogen deposition (de Vries et al., 2009; Devaraju et al., 2016; Huntzinger et al., 2017) or the synergy between increasing nitrogen deposition and atmospheric CO_2 concentration (O'Sullivan et al., 2019) could have also contributed to the increasing global net land CO_2 sink. The effects of climate change alone on the global net land CO_2 sink is so divergent that even the signs of the effects are not the same across DGVMs (e.g. Huntzinger et al., 2017).

Lower fire emission of CO_2 and enhanced vegetation carbon uptake due to reduced global burned area have contributed to the increasing global net land CO_2 sink in the recent decade (Arora and Melton, 2018; Yin et al., 2020) (*low to medium confidence*). Satellite observations reveal a declining trend in global burned area by about 20% over past two decades (Andela et al., 2017; Earl and Simmonds, 2018; Forkel et al., 2019b; Jones et al., 2020), a trend most pronounced in regions like northern Africa (Forkel et al., 2019; Zubkova et

ACCEPTED VERSION SUBJECT TO FINAL EDITS

al., 2019; Bowman et al., 2020; Jones et al., 2020) and Mediterranean Europe (Turco et al., 2016). However, burned area trends are highly heterogeneous regionally with increasing trends reported in regions like western United States (Holden et al., 2018a; Abatzoglou et al., 2019) and southeastern Australia (Canadell et al., 2020). Some regions (e.g. Amazon basin and Australia) experienced record-breaking fire events in 2019 and 2020 (e.g. Boer et al., 2020), whose effects on burned area trends remain to be explored. The burned area trends were primarily attributed to both human-induced climate change and human activities (Jolly et al., 2015; Andela et al., 2017; Holden et al., 2018b; Turco et al., 2018; Teckentrup et al., 2019; Bowman et al., 2020), as well as changing frequency of lightning in the boreal region (Veraverbeke et al., 2017). In addition to changes in the burned area, fire dynamics could affect trend in land-atmosphere CO_2 exchange indirectly through increasing concentration of air pollutants (Yue and Unger, 2018; Lasslop et al., 2019; see Section 6.3.4 for impacts of ozone and aerosol on the carbon cycle).

Significant uncertainties remain on land CO_2 sink partition of processes due to challenges in reconciling multiple-scale evidence from experiments to the globe (Fatichi et al., 2019; Walker et al., 2020), due to large spatial and inter-model differences in diagnosing dominant driving factors affecting the net land CO_2 sink (Huntzinger et al., 2017; Fernández-Martínez et al., 2019), and due to model deficiency in process representations (He et al., 2016). Nitrogen dynamics, a major gap in DGVMs identified in AR5, have now been incorporated in about half of the DGVMs contributing to the carbon budget of the Global Carbon Project (GCP) (see Le Quéré et al., (2018a) for model characteristics) and a growing number of ESMs (Arora et al., 2020). However, as the representations of carbon-nitrogen interactions vary greatly among models, large uncertainties remain on how nitrogen cycling regulates the response of ecosystem carbon uptake to higher atmospheric CO_2 (Davies-Barnard et al., 2020; Walker et al., 2015; Wieder et al., 2019; Meyerholt et al., 2020; see Section 5.4.1). Fire modules have been incorporated into 10 of 16 DGVMs contributing to the global carbon budget (Le Quéré et al., 2018a), and a growing number of models have representations of human ignitions and fire suppression processes (Rabin et al., 2017; Teckentrup et al., 2019). There are also growing DGVM developments to include management practices (Pongratz et al., 2018b) and the effects of secondary forest regrowth (Pugh et al., 2019a), though models still under represent intensively managed ecosystems, such as croplands and managed forests (Guanter et al., 2014; Thurner et al., 2017). Processes that have not yet played a significant role in the land CO_2 sink of the past decades but can grow in importance, include permafrost (Section 5.4) and peatlands dynamics (Dargie et al., 2017; Gibson et al., 2019), have also been incorporated in some DGVMs (Koven et al., 2015a; Burke et al., 2017a; Guimberteau et al., 2018). Growing numbers and varieties of Earth observations are being jointly used to drive and benchmark models, helping further identify key processes missing or mechanisms poorly represented in the current generation of DGVMs (e.g. Collier et al., 2018).

[START FIGURE 5.10 HERE]

Figure 5.10: Trends of the net land CO_2 sink and related vegetation observations during 1980–2019. (a) Net land CO_2 sink. The residual net land CO_2 sink is estimated from the global CO_2 mass balance (fossil fuel emission minus atmospheric CO_2 growth rate and ocean CO_2 sink). Inversions indicate the net land CO_2 sink estimated by an ensemble of four atmospheric inversions. Dynamic Global Vegetation Models (DGVMs) indicate the mean net land CO_2 sink estimated by 17 dynamic global vegetation models driven by climate change, rising atmospheric CO_2, land use change and nitrogen deposition change (for carbon-nitrogen models). The positive values indicate net CO_2 uptake from the atmosphere. (b) Normalised difference vegetation index (NDVI). The anomaly of global area-weighted NDVI observed by AVHRR and MODIS satellite sensors. AVHRR data are accessible during 1982–2016 and MODIS data are accessible during 2000–2018. (c) Near-infrared reflectance of vegetation (NIRv) and contiguous solar-induced chlorophyll fluorescence (CSIF). The standardised anomaly of area-weighted NIRv during 2001-2018 (Badgley et al., 2017) and CSIF during 2000-2018 (Zhang et al., 2018). (d) Gross primary production (GPP). The GPP from Cheng et al. (2017), DGVMs and MODIS GPP product (MOD17A3). GPP from Cheng et al. (2017) is based on an analytical model driven by climate change, rising atmospheric CO_2, AVHRR leaf area index datasets and evapotranspiration datasets. GPP from DGVMs is the ensemble mean global GPP estimated by the same 17 DGVMs that provide the net land CO_2 sink estimates. Shaded area indicates 1–σ inter-model spread except for atmospheric inversions, whose ranges were used due to limited number of models. Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

[END FIGURE 5.10 HERE]

5.2.1.4.2 Interannual variability in land-atmosphere CO_2 exchange

AR5 stated that the interannual variability of the atmospheric CO_2 growth rate is dominated by tropical land ecosystems. A set of new satellite measurements applied to assess the variability of the tropical land carbon balance since AR5 (Ciais et al., 2013) confirm this statement, including satellite column CO_2 measurements, estimating recent anomalous land-atmosphere CO_2 exchange induced by El Niño at continental scale (e.g. Liu et al., 2017; Palmer et al., 2019), and L-band vegetation optical depth, estimating tropical above-ground biomass carbon stock changes (Fan et al., 2019). In addition, based on medium evidence and medium agreement between studies with DGVMs and atmospheric inversions, semi-arid ecosystems over the tropical zones have a larger contribution to interannual variability in global land-atmosphere CO_2 exchange than moist tropical forest ecosystems (Poulter et al., 2014; Ahlstrom et al., 2015; Piao et al., 2020) (*low to medium confidence*).

Understanding the mechanisms driving interannual variability in the carbon cycle has the potential to provide insights into whether and to what extent the carbon cycle can affect the climate (carbon-climate feedback), with particular interests over the highly climate-sensitive tropical carbon cycle (e.g. Cox et al., 2013a; Fang et al., 2017; Humphrey et al., 2018; Jung et al., 2017a; Malhi et al., 2018; Wang et al., 2014; see Section 5.4). Consistent findings from studies with atmospheric inversions, satellite observations and DGVMs (e.g. Malhi et al., 2018; Rödenbeck et al., 2018) lead to *high confidence* that the tropical net land CO_2 sink is reduced under warmer and drier conditions, particularly during El Niño events. Interannual variations in tropical land-atmosphere CO_2 exchange are significantly correlated with anomalies of tropical temperature, water availability and terrestrial water storage (Wang et al., 2014; Jung et al., 2017; Humphrey et al., 2018; Piao et al., 2020), whose relative contribution are difficult to separate due to covariations between these climatic factors. At continental scale, the dominant climatic driver of interannual variations of tropical land-atmosphere CO_2 exchange was temperature variations (Figure 5.11; Piao et al., 2020), which could partly result from the spatial compensation of the water availability effects on land-atmospheric CO_2 exchange (Jung et al., 2017).

[START FIGURE 5.11 HERE]

Figure 5.11: Interannual variation in detrended anomalies of the net land CO_2 sink and land surface air temperature during 1980–2019. Correlation coefficients between the net land CO_2 sink anomalies and temperature anomalies are show on the right bar plots. The net land CO_2 sink is estimated by four atmospheric inversions (blue) and fifteen Dynamic Global Vegetation Models (DGVMs) (green), respectively (Friedlingstein et al., 2020). Solid blue and green lines show model mean detrended anomalies of the net land CO_2 sink. The ensemble mean of DGVMs is bounded by the 1–σ inter-model spread in each large latitude band (North 30°N–90°N, Tropics 30°S–30°N, South 90°S–30°S) and the globe. The ensemble mean of atmospheric inversions is bounded by model spread. For each latitudinal band, the anomalies of the net land CO_2 sink and temperature (orange) were obtained by removing the long-term trend and seasonal cycle. A 12-month running mean was applied to reduce high-frequency noise. The bars in the right panels show correlation coefficients between the net land CO_2 sink anomalies and temperature anomalies for each region. Two asterisks indicate $P<0.01$, and one indicates $P<0.05$. Grey shaded area shows the intensity of El Niño southern oscillation (ENSO) as defined by the Niño 3.4 index. Two volcanic eruptions (El Chichón eruption and Pinatubo eruption) are indicated with light blue dashed lines. Temperature data are from the Climatic Research Unit (CRU), University of East Anglia (Harris et al., 2014). Anomalies were calculated following Patra et al. (2005), but using 12-month low-pass filter and detrended to obtain interannual variations. Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

[END FIGURE 5.11 HERE]

[START CROSS-CHAPTER BOX 5.1]

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Cross-Chapter Box 5.1: Interactions between the carbon and water cycles, particularly under drought conditions

Contributors: Josep G Canadell (Australia), Philippe Ciais (France), Hervé Douville (France), Sabine Fuss (Germany), Robert B Jackson (USA), Annalea Lohila (Finland), Shilong Piao (China), Sonia I. Seneviratne (Switzerland), Sergio M. Vicente-Serrano (Spain), Sönke Zaehle (Germany)

This box presents an assessment of interactions between the carbon and water cycles that influence the dynamics of the biosphere and its interaction with the climate system. It also highlights carbon-water trade-offs arising from the use of land-based climate mitigation options. Individual aspects of the interactions between the carbon and water cycles are addressed in separate chapters (Sections 5.2.1, 5.4.1, 8.2.3, 8.3.1, 8.4.1, 11.6). The influence of wetlands and dams on methane emissions is assessed elsewhere (Sections 5.2.2, 5.4.7, 8.3.1), as well as the consequences of permafrost thawing (Box 5.1, Section 9.5.2) and/or increased flooding (Sections 8.4.1, 11.5, 12.4) on wetland extent in the northern high latitudes and wet tropics.

Does elevated CO_2 alleviate the impacts of drought?

Increasing atmospheric CO_2 concentration enhances leaf photosynthesis and drives a partial closure of leaf stomata, leading to higher water-use efficiency (WUE) at the leaf, canopy to ecosystem scales (Norby and Zak, 2011; De Kauwe et al., 2013; Fatichi et al., 2016; Knauer et al., 2017; Mastrotheodoros et al., 2017). Since AR5 (Box 6.3), a growing body of evidence from tree-ring and carbon isotopes further confirms an increase of plant water-use efficiency over decadal to centennial time scales, with some evidence for a stronger enhancement of photosynthesis compared to stomatal reductions (Frank et al., 2015; Guerrieri et al., 2019; Adams et al., 2020).

Multiple lines of evidence suggest that WUE has increased in near proportionality to atmospheric CO_2 (*high confidence*), at a rate generally consistent with Earth System Models (ESMs), despite variation in the WUE response to CO_2 (De Kauwe et al., 2013; Frank et al., 2015; Keeling et al., 2017; Lavergne et al., 2019; Walker et al., 2020). Both field-scale CO_2 enrichment experiments and process models show the effect of physiologically induced water savings, particularly under water limiting conditions (De Kauwe et al., 2013; Farrior et al., 2015; Lu et al., 2016; Roy et al., 2016). Plants can also benefit from reduced drought stress due to enhanced CO_2 without ecosystems-scale water savings (Jiang et al., 2021). This increased WUE offsets to some extent the effects of enhanced vapor pressure deficit (VPD) on plant transpiration (Bobich et al., 2010; Creese et al., 2014; Jiao et al., 2019), but will have limited effect on ameliorating plant water stress during extreme drought events (Xu et al., 2016; Menezes-Silva et al., 2019; Liu et al., 2020b), when leaf stomata is governed primarily by soil moisture (Roy et al., 2016).

Leaf stomata closure can have large effects on land freshwater availability because of reduced plant transpiration leading in some regions to higher soil moisture and runoff (Roderick et al., 2015; Milly and Dunne, 2016; Yang et al., 2019c). However, increased water availability is often not realized because other CO_2 physiological effects that enhance ecosystem evapotranspiration might offset the gains. These effects include plant growth and leaf area expansion (Ainsworth and Long, 2005; Ukkola et al., 2016; McDermid et al., 2021), lengthening of the vegetative growing season (Frank et al., 2015; Lian et al., 2021), and the effects of stomatal closure on near-surface atmosphere that leads to increased air temperature and vapor-pressure deficits (Berg et al., 2016; Vogel et al., 2018; Zhou et al., 2019; Grossiord et al., 2020).

ESMs show no consensus about the net hydrological response to physiological CO_2 effects. Some studies show water savings as a consequence of the CO_2 effects on leaf stomata closure (Swann et al., 2016; Lemordant et al., 2018), while other studies show that increased leaf area offsets the gains from increased WUE (Mankin et al., 2019). However, these projections are subject to ESM uncertainties to quantify transpiration (Lian et al., 2021), among them the correct representations of plant hydraulic architecture such as changes in xylem anatomical properties and deep rooting (Nie et al., 2013; Liu et al., 2020b).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

In conclusion, it is *very likely* that elevated CO_2 leads to increased WUE at the leaf level concurrent with enhanced photosynthesis. Increased CO_2 concentrations alleviate the effects of water deficits on plant productivity (*medium confidence*) but there is *low confidence* on its role under extreme drought conditions. There is *low confidence* that increased WUE by vegetation will substantially reduce global plant transpiration and diminish the frequency and severity of soil moisture and streamflow deficits associated with the radiative effect of higher CO_2 concentrations.

How does drought affect the terrestrial CO_2 sink?

Water availability controls the spatial distribution of photosynthesis (gross primary productivity, GPP) over a larger part of the globe (Beer et al., 2010) and, at local scale, drought decreases GPP more than respiration (Schwalm et al., 2012) over most ecosystem types. This makes water availability a major climatic driver of variability in net ecosystem exchange (Jung et al., 2017; Humphrey et al., 2018). In addition to suppressing photosynthesis, field evidence suggests that droughts reduce the land CO_2 sink also through increasing forest mortality and promoting wildfire (Allen et al., 2015; Brando et al., 2019; Abram et al., 2021).

At the global scale, interannual variability in the atmospheric CO_2 growth rate and global-scale terrestrial water storage from satellite shows that a lower global net land CO_2 sink is associated with below-average terrestrial water storage (Humphrey et al., 2018). Atmospheric inversions based on surface and satellite column CO_2 measurements show significant carbon release during drought events in pan-tropic areas (Phillips et al., 2009; Gatti et al., 2014; Liu et al., 2017a; Palmer et al., 2019a). Regional extreme droughts in the mid-latitudes also lead to decreased GPP and land CO_2 sink (Ciais et al., 2005; Wolf et al., 2016; Peters et al., 2020b; Flach et al., 2021). Droughts cannot be compensated by equivalent wet anomalies because of the non-linear response of the terrestrial carbon uptake to soil moisture (Green et al., 2019).

Uncertainties remain on the magnitude of sensitivity of the land carbon fluxes to droughts. Global studies indicate stronger control of soil moisture to variations in satellite proxies of GPP than VPD (Stocker et al., 2019; Liu et al., 2020b). However, given that VPD increases exponentially with atmospheric warming, some studies suggest that the importance of VPD in stomatal regulation will become increasingly more important under warmer climate (Novick et al., 2016; Grossiord et al., 2020). It is difficult to isolate the relative contributions of warmer temperature, higher VPD and lower soil moisture. This is because land-atmosphere feedbacks cause a simultaneous increase of plant evaporative demand and of root zone water deficit impairing plant root uptake (Berg et al., 2016). These physiological responses can be further compounded by drought legacies (Anderegg et al., 2015), changes in structure and population dynamics due to forest mortality (McDowell et al., 2020), disturbances associated with drought (fire, insects damage) (Anderegg et al., 2020) and possible trade-offs between resistance and resilience (Li et al., 2020b). Nonetheless, ESMs suggest that increased drought effects under very high levels of global warming (ca. 4°C at the end of the 21st century) contribute to the reduced efficiency of the land sink (Green et al., 2019).

In conclusion, there is *high confidence* that the global net land CO_2 sink is reduced on interannual scale when regional-scale reductions in water availability associated with droughts occur, particularly in tropical regions. There is also *high confidence* that the global land sink will become less efficient due to soil moisture limitations and associated drought conditions in some regions for high emission scenarios, specially under global warming above 4°C. However, there is *low confidence* on how these water cycle feedbacks will play out in lower emission scenarios (at 2°C global warming or lower) due to uncertainties in regional rainfall changes and the balance between the CO_2 fertilisation effect, through WUE, and the radiative impacts of greenhouse gases.

What are the limits of carbon dioxide removal from a water cycle perspective?

Carbon dioxide removal (CDR) options based on terrestrial carbon sinks will require the appropriation of significant amounts of water at the landscape level. Most mitigation pathways that seek to limit global warming to 1.5°C or less than 2°C require the removal of about 30 to 300 GtC from the atmosphere by 2100 (Rogelj et al., 2018b). Bioenergy with carbon capture and storage (BECCS), and afforestation/reforestation are the dominant CDR options used in climate stabilisation scenarios implying large requirements for land and water (Section 5.6; (Beringer et al., 2011; Boysen et al., 2017b; Fajardy and Mac Dowell, 2017; Jans et

ACCEPTED VERSION SUBJECT TO FINAL EDITS

al., 2018; Séférian et al., 2018b; Yamagata et al., 2018; Stenzel et al., 2019). A review of freshwater requirements for irrigating biomass plantations shows a range between 15 and 1250 km^3 per GtC^{-1} of biomass harvest. This is equivalent to a water requirement of 99–8250 km^3 for the median BECCS deployment of around 3.3 $GtCyr^{-1}$ (Smith et al., 2016) in <2°C-scenarios (Stenzel et al., 2021), assuming that biomass is converted to electricity which is substantially less efficient than to heat. These large ranges are the result of different assumptions about the type of biomass and yield improvements, management, and land availability. The use of alternative feedstocks, such as wastes, residues and algae, would lead to smaller water requirements (Smith et al., 2019).

Most of the water consumed in BECCS is used to grow the feedstock, with carbon capture and storage constituting a smaller portion across all crops (Rosa et al., 2020), with an estimated evaporative loss of 260 $km^3\ yr^{-1}$ for 3.3 GtC yr^{-1} (Smith et al., 2016). The same authors also estimate water use for CDR through afforestation at 1040 $km^3\ yr^{-1}$ for 3.3 GtC yr^{-1}, including interception and transpiration and adjusted for the original land cover's water use.

The impacts of different CDR options on the water cycle depend crucially on regional climate, prior land cover, and scale of deployment (Trabucco et al., 2008). Extensive irrigation for afforestation in drier areas will have larger downstream impacts than in wetter regions with the difference in water use between the afforested landscapes and its previous vegetation determining the level of potential impacts on evapotranspiration and runoff (Jackson et al., 2005; Teuling et al., 2017). Afforestation and reforestation sometimes enhances precipitation through atmospheric feedbacks such as increased convection, at least in the tropics (Ellison et al., 2017) and the increase in precipitation can in some regions even cancel out the increased evapotranspiration (Li et al., 2018).

In conclusion, extensive deployment of BECCS and afforestation/reforestation will require larger amounts of freshwater resources than used by the previous vegetation, altering the water cycle at regional scales (*high confidence*). Consequences of high water consumption on downstream uses, biodiversity, and regional climate depend on prior land cover, background climate conditions, and scale of deployment (*high confidence*). Therefore, a regional approach is required to determine the efficacy and sustainability of CDR projects.

[END CROSS-CHAPTER BOX 5.1]

5.2.1.5 CO_2 Budget

The global CO_2 budget (Figure 5.12) encompasses all natural and anthropogenic CO_2 sources and sinks. Table 5.1 shows the perturbation of the global carbon mass balance between reservoirs since the beginning of the industrial era, circa 1750.

Since AR5 (Ciais et al., 2013), a number of improvements have led to a more constrained carbon budget presented here. Some new additions include: (i) the use of independent estimates for the residual carbon sink on natural terrestrial ecosystems (Le Quéré et al., 2018a), (ii) improvements in the estimates of emissions from cement production (Andrew, 2019) and the sink associated with cement carbonation (Cao et al., 2020), (iii) improved and new emission estimates from forestry and other land use (Hansis et al., 2015; Gasser et al., 2020), (iv) the use of ocean observation-based sink estimates and a revised river flux partition between hemisphere (Friedlingstein et al., 2020); and (v) the expansion of constraints from atmospheric inversions, both based on surface networks and the use of satellite retrievals.

The budget, based on the annual assessment by the GCP (Friedlingstein et al., 2020), uses independent estimates of all major flux components: fossil fuel and carbonate emissions (E_{FOS}), CO_2 fluxes from Forestry and other Land Use (E_{LULUCF}), the growth rate of CO_2 in the atmosphere (G_{atm}), and the ocean (S_{ocean}) and natural land (S_{land}) CO_2 sinks. An imbalance term (B_{Imb}) is required to ensure mass balance of the source and sinks that have been independently estimated: $E_{FOS} + E_{LULUCF} = G_{atm} + S_{ocean} + S_{land.} + B_{Imb.}$ All estimates are reported with 1 standard deviation (±1σ, 1 sigma) representing a likelihood of 68%.

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Over the past decade (2010–2019), 10.9 ± 0.9 PgC yr^{-1} were emitted from human activities which were distributed between three Earth system components: 46% accumulated in the atmosphere (5.1 ± 0.02 PgC yr^{-1}), 23% was taken up by the ocean (2.5 ± 0.6 PgC yr^{-1}) and 31% was stored by vegetation in terrestrial ecosystems (3.4 ± 0.9 PgC yr^{-1}) (Table 5.1). There is a budget imbalance of 0.1 PgCyr^{-1} which is within the uncertainties of the other terms. Over the industrial era (1750–2019), the total cumulative CO_2 fossil fuel and industry emissions were 445 ± 20 PgC, and the LULUCF flux (=net land use change in Figure 5.12) was 240 ± 70 PgC (*medium confidence*). The equivalent total emissions (685 ± 75 PgC) was distributed between the atmosphere (285 ± 5 PgC), oceans (170 ± 20 PgC) and land (230 ± 60 PgC) (Table 5.1), with a budget imbalance of 20 PgC.

This budget (Table 5.1) does not explicitly account for source/sink dynamics due to carbon cycling in the land–ocean aquatic continuum comprising freshwaters, estuaries, and coastal areas. Natural and anthropogenic transfers of carbon from soils to freshwater systems are significant (2.4–5.1 PgC yr^{-1}) (Regnier et al., 2013a; Drake et al., 2018). Some of the carbon is buried in freshwater bodies (0.15 PgC) (Mendonça et al., 2017), and a significant proportion returns to the atmosphere via outgassing from lakes, rivers and estuaries (Raymond et al., 2013; Regnier et al., 2013a; Lauerwald et al., 2015). The net export of carbon from the terrestrial domain to the open oceans is estimated to be 0.80 PgC yr^{-1} (*medium confidence)*, based on the average of (Jacobson et al., 2007; Resplandy et al., 2018b) and corrected to account for 0.2 PgC buried in ocean floor sediments. These terms are included in Figure 5.12. Inclusion of other smaller fluxes could further constrain the carbon budget (Ito, 2019; Friedlingstein et al., 2020).

[START FIGURE 5.12 HERE]

Figure 5.12: Global carbon (CO_2) budget (2010-2019). Yellow arrows represent annual carbon fluxes (in PgC yr^{-1}) associated with the natural carbon cycle estimated for the time prior to the industrial era, around 1750. Pink arrows represent anthropogenic fluxes averaged over the period 2010–2019. The rate of carbon accumulation in the atmosphere is equal to net land-use change emissions, including land management (called LULUCF in the main text) plus fossil fuel emissions, minus land and ocean net sinks (plus a small budget imbalance, Table 5.1). Circles with yellow numbers represent pre-industrial carbon stocks in PgC. Circles with pink numbers represent anthropogenic changes to these stocks (cumulative anthropogenic fluxes) since 1750. Anthropogenic net fluxes are reproduced from Friedlingstein et al., (2020). The relative change of *gross photosynthesis* since pre-industrial times is based on 15 DGVMs used in Friedlingstein et al., (2020). The corresponding emissions by *Total respiration and fire* are those required to match the *net land flux*, exclusive of net land-use change emissions which are accounted for separately. The cumulative change of anthropogenic carbon in the terrestrial reservoir is the sum of carbon cumulatively lost by net land use change emissions, and net carbon accumulated since 1750 in response to environmental drivers (warming, rising CO_2, nitrogen deposition). The adjusted gross natural ocean-atmosphere CO_2 flux was derived by rescaling the value in figure 1 of (Sarmiento and Gruber, 2002) of 70 PgC/yr by the revised estimate of the bomb ^{14}C inventory in the ocean. The original bomb ^{14}C inventoy yielded an average global gas transfer velocity of 22 cm/hr; the revised estimate is 17cm/h leading to 17/22*70=54. Dissolved organic carbon reservoir and fluxes from (Hansell et al., 2009). Dissolved inorganic carbon exchanges between surface and deep ocean, subduction and obduction from (Levy et al., 2013) Levy et al. 2013. Export production and flux from (Boyd et al., 2019). NPP and remineralisation in surface layer of the ocean from (Kwiatkowski et al., 2020; Séférian et al., 2020). Deep ocean reservoir from (Keppler et al., 2020). Note that the mass balance of the two ocean carbon stocks *surface ocean* and *intermediate and deep ocean* includes a yearly accumulation of anthropogenic carbon (not shown). Fossil fuel reserves are from (BGR, 2019); fossil fuel resources are 11,490 PgC for coal, 6,780 PgC for oil, and 365 PgC for natural gas. Permafrost region stores are from (Hugelius et al., 2014; Strauss et al., 2017; Mishra et al., 2021) (see also Box 5.1) and soil carbon stocks outside of permafrost region from Batjes, (2016); Jackson et al., (2017). Biomass stocks (range of seven estimates) are from Erb et al., (2018). Sources for the fluxes of the continuum land-to-ocean are provided in main text and adjusted within the ranges of the various assessment to balance the budget (section 5.2.1.5).

[END FIGURE 5.12 HERE]

[START TABLE 5.1 HERE]

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Table 5.1: Global anthropogenic CO_2 budget accumulated since the industrial revolution (onset in 1750) and averaged over the 1980s, 1990s, 2000s, and 2010s. By convention, a negative ocean or land to atmosphere CO_2 flux is equivalent to a gain of carbon by these reservoirs. The table does not include natural exchanges (e.g. rivers, weathering) between reservoirs. Uncertainties represent the 68% confidence interval (Friedlingstein et al., 2020).

5.2.2 CH_4: Trends, Variability and Budget

Methane is a much more powerful greenhouse gas than CO_2 (Chapter 7) and participates in tropospheric air chemistry (Chapter 6). The CH_4 variability in the atmosphere is mainly the result of the net balance between the sources and sinks on the Earth's surface and chemical losses in the atmosphere. Atmospheric transport evens out the regional CH_4 differences between different parts of the Earth's atmosphere. The steady-state lifetime is estimated to be 9.1 ± 0.9 (Chapter 6, Section 3.1). About 90% of the loss of atmospheric CH_4 occurs in the troposphere by reaction with hydroxyl (OH) radical, 5% by bacterial soil oxidation, and the rest 5% by chemical reactions with OH, excited state oxygen (O^1D), and atomic chlorine (Cl) in the stratosphere (Saunois et al., 2020). Methane has large emissions from both natural and anthropogenic origins, but a clear demarcation of their nature is difficult because of the use and conversions of the natural ecosystem for human activities. The largest natural sources are from wetlands, freshwater and geological process, while the largest anthropogenic emissions are from enteric fermentation and manure treatment, landfills and waste treatment, rice cultivation and fossil fuel exploitation (Table 5.2). In the past two centuries, CH_4 emissions have nearly doubled, predominantly human driven since 1900, and persistently exceeded the losses (*virtually certain*), thereby increasing the atmospheric abundance as evidenced from the ice core and firn air measurements (Ferretti et al., 2005; Ghosh et al., 2015).

This section discusses both bottom-up and top-down estimates of emissions and sinks. Bottom-up estimates are based on empirical upscaling of point measurements, emission inventories and dynamical model simulations, while top-down estimates refer to those constrained by atmospheric measurements and chemistry-transport models in inversion systems. Since the AR5, a larger suite of atmospheric inversions using both in situ and remote sensing measurement have led to better understanding of the regional CH_4 sources (Cross-Chapter Box 5.2). New ice core measurements of ^{14}C-CH_4 are used for estimating the geological sources of CH_4 (Table 5.2). Compared to the IPCC SRCCL (IPCC, 2019a; Jia et al., 2019), we provide a whole atmospheric sources-sinks budget consisting of all emissiones and losses.

5.2.2.1 Atmosphere

Since the start of direct measurements of CH_4 in the atmosphere in the 1970s (Figure 5.13), the highest

ACCEPTED VERSION SUBJECT TO FINAL EDITS

growth rate was observed from 1977 to 1986 at 18 ± 4 ppb yr^{-1} (multi-year mean and 1 standard deviation) (Rice et al., 2016). This rapid CH_4 growth followed the green revolution with increased crop-production and a fast rate of industrialisation that caused rapid increases in CH_4 emissions from ruminant animals, rice cultivation, landfills, oil and gas industry and coal mining (Ferretti et al., 2005; Ghosh et al., 2015; Crippa et al., 2020). Due to increases in oil prices in the early 1980s, emissions from gas flaring declined significantly (Stern and Kaufmann, 1996). This explains the first reduction in CH_4 growth rates from 1985 to 1990 (Steele et al., 1992; Chandra et al., 2021). Further reductions in emission occurred following the Mt Pinatubo eruption in 1991 that triggered a reduction in CH_4 growth rate through a decrease in wetland emissions driven by lower surface temperatures due to the scattering aerosols (Bândă et al., 2016; Chandra et al., 2021). In the late 1990s through 2006 there was a temporary pause in the CH_4 growth rate, with higher confidence on its causes than the in AR5: emission from the oil and gas sectors declined by about 10 Tg yr^{-1} through the 1990s, and atmospheric CH_4 loss steadily increased (Dlugokencky et al., 2003; Simpson et al., 2012; Crippa et al., 2020; Höglund-Isaksson et al., 2020; Chandra et al., 2021). Methane growth rate began to increase again at 7 ± 3 ppb yr^{-1} during 2007–2016, the causes of which are highly debated since the AR5 (Rigby et al., 2008; Dlugokencky et al., 2011; Dalsøren et al., 2016; Nisbet et al., 2016; Patra et al., 2016; Schaefer et al., 2016; Schwietzke et al., 2016; Turner et al., 2017; Worden et al., 2017; He et al., 2020); studies disagree on the relative contribution of thermogenic, pyrogenic and biogenic emission processes and variability in tropospheric OH concentration. The renewed CH_4 increase is accompanied by a reversal of $\delta^{13}C$ trend to more negative values post 2007; opposite to what occurred in the 200 years prior (Ferretti et al., 2005; Ghosh et al., 2015; Schaefer et al., 2016; Schwietzke et al., 2016; Nisbet et al., 2019), suggesting an increasing contribution from animal farming, landfills and waste, and a slower increase in emissions from fossil fuel exploitation since the early 2000s (Patra et al., 2016; Jackson et al., 2020; Chandra et al., 2021). A comprehensive assessment of the CH_4 growth rates over the past 4 decades is presented in the Cross-Chapter Box 5.2.

[START FIGURE 5.13 HERE]

Figure 5.13: Time series of CH_4 concentrations, growth rates and isotopic composition. a) CH_4 concentrations, b) CH_4 growth rates, c) δ^{13}-CH_4. Data from selected site networks operated by NOAA (Dlugokencky et al., 2003), AGAGE (Prinn et al., 2018) and PDX (Portland State University) (Rice et al., 2016). To maintain clarity, data from many other measurement networks are not included here, and all measurements are shown in WMO X2004ACH_4 global calibration standard. Global mean values of XCH_4 (total-column), retrieved from radiation spectra measured by the greenhouse gases observation satellite (GOSAT) are shown in panels (a) and (b). Cape Grim Observatory (CGO; 41°S, 145°E) and Trinidad Head (THD; 41°N, 124°W) data are taken from the AGAGE network, NOAA global and northern hemispheric (NH) means for $\delta^{13}C$ are calculated from 10 and 6 sites, respectively. The PDX data adjusted to NH (period: 1977–2000) are merged with THD (period: 2001–2019) for CH_4 concentration and growth rate analysis, and PDX and NOAA NH means of $\delta^{13}C$ data are used for joint interpretation of long-term trends analysis. The multivariate ENSO index (MEI) is shown in panel (b). Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

[END FIGURE 5.13 HERE]

5.2.2.2 Anthropogenic CH_4 emissions

The positive gradient between CH_4 at Cape Grim, Australia (41°S) and Trinidad Head, USA (41°N), and the bigger difference between Trinidad Head and global mean CH_4 compared to that between global mean CH_4 and Cape Grim, strongly suggest that the northern hemisphere is the dominant origin of anthropogenic CH_4 emissions (Figure 5.13). The loss rate of CH_4 in troposphere does not produce a large positive north-south hemispheric gradient in CH_4 due to parity in hemispheric mean OH concentration (Patra et al., 2014) or in the case of greater OH concentrations in the northern than the southern hemisphere as simulated by the chemistry-climate models (Naik et al., 2013). Coal mining contributed about 35% of the total CH_4 emissions from all fossil fuel related sources. Top-down estimates of fossil fuel emissions (106 Tg yr^{-1}) are smaller than bottom-up estimates (115 Tg yr^{-1}) during 2008–2017 (Table 5.2). Inventory-based estimates suggest that

ACCEPTED VERSION SUBJECT TO FINAL EDITS

CH_4 emissions from coal mining increased by 17 Tg yr^{-1} between the periods 2002–2006 and 2008–2012, with a dominant contribution from China (Peng et al., 2016; Crippa et al., 2020; Höglund-Isaksson et al., 2020). Furthermore, top-down estimates suggest emissions from China's coal mines have continued to grow at a slower rate after 2010 (Miller et al., 2019; Chandra et al., 2021). Emissions from oil and gas extraction and use decreased in the 1980s and 1990s, but increased in the 2000s and 2010s (Dlugokencky et al., 1994; Stern and Kaufmann, 1996; Howarth, 2019; Crippa et al., 2020). The attribution to multiple CH_4 source using spatially aggregated atmospheric $\delta^{13}C$ data remained underdetermined to infer the global total emissions from the fossil fuel industry, biomass burning and agriculture (Rice et al., 2016; Schaefer et al., 2016; Schwietzke et al., 2016; Worden et al., 2017; Thompson et al., 2018).

In the agriculture and waste sectors (Table 5.2), livestock production has the largest emission source (109 Tg yr^{-1} in 2008–2017) dominated by enteric fermentation by about 90%. Methane is formed during the storage of manure, when anoxic conditions are developed (Hristov et al., 2013). Emissions from enteric fermentation and manure have increased gradually from about 87 Tg yr^{-1} in 1990–1999 to 109 Tg yr^{-1} in 2008–2017 mainly due to the increase in global total animal numbers. Methane production in livestock rumens (cattle, goats, sheep, water buffalo) are affected by the type, amount and quality of feeds, energy consumption, animal size, health and growth rate, meat and milk production rate, and temperature (Broucek, 2014; Williams et al., 2015; IPCC SRCCL 5.4.3). Waste management and landfills produced 64 Tg yr^{-1} in 2008–2017, with global emissions increasing steadily since the 1970s and despite significant declines in US, western Europe and Japan (Crippa et al., 2020; Höglund-Isaksson et al., 2020).

Emissions from rice cultivation decreased from about 45 Tg yr^{-1} in the 1980s to about 29 Tg yr^{-1} in the 2000-2009 but increased again slightly to 31 Tg yr^{-1} during 2008–2017 based inventories data. However, ecosystem models showed a gradual increase with time due to climate change (*limited evidence, low agreement*) (Crippa et al., 2020; Höglund-Isaksson et al., 2020; Ito, 2020).

Biomass burning and biofuel consumption (including both natural and anthropogenic processes) caused at least 30 Tg yr^{-1} emissions during 2008–2017 and constituted up to about 5% of global anthropogenic CH_4 emissions. Methane emissions from open biomass burning decreased during the past two decades mainly due to reduction of burning in savanna, grassland and shrubland (van der Werf et al., 2017; Worden et al., 2017). There is recent evidence from the tropics that fire occurrence is non-linearly related to precipitation, implying that severe droughts will increase CH_4 emissions from fires, particularly from the degraded peatlands (Field et al., 2016).

[START TABLE 5.2 HERE]

Table 5.2: **Global CH_4 budget.** Sources and sinks of CH_4 for the two recent decades from bottom–up and top-down estimations (in Tg CH_4 yr^{-1}). The data are updated from (Saunois et al., 2020), for the bottom-up anthropogenic emissions (FAO, 2019; US EPA, 2019; Crippa et al., 2020; Höglund-Isaksson et al., 2020), top-down geological emissions (Schwietzke et al., 2016; Petrenko et al., 2017; Hmiel et al., 2020), and top-down sinks from 7 selected inverse models. The means (min-max) with outliers removed from both the range and the means are given. Outliers defined as >75th percentile + 3 × the interquartile range or < 25th percentile – 3 × the interquartile range. The top-down budget imbalances are calculated for each model separately and averaged. Note also the round-off error for the sources and sinks, which sometimes leads to last digit mismatch in the sums. For detailed information on datasets, see further details on data table 5.SM.6.

5.2.2.3 Land Biospheric Emissions and Sinks

Freshwater wetlands are the single largest global natural source of CH_4 into the atmosphere, accounting for about 26% of the total CH_4 source (*robust evidence, medium agreement*). Progress has been made since AR5 (Ciais et al., 2013) in better constraining freshwater lake and river emissions and reducing double counting with wetland emissions. Bottom-up and top-down estimates for 2008–2017 are 149 and 180 Tg yr^{-1}, respectively, with a top-down uncertainty range of 159–199 Tg yr^{-1} (Table 5.2). The large uncertainties stem from challenges in mapping wetland area and temporal dynamics, and in scaling methane production, transport and consumption processes, that are measured with small chambers or flux towers, to landscape estimates (Pham-Duc et al., 2017). Both the top-down and bottom-up estimates presented in Table 5.2 indicate little increase in wetland CH_4 emissions during the last three decades, with the new estimates being slightly smaller than in AR5 due to updated wetland maps and ecosystem model simulations (Melton et al., 2013; Poulter et al., 2017). The wetland emissions show strong interannual variability due to the changes in inundated land area, air temperature and microbial activity (Bridgham et al., 2013). Present terrestrial ecosystem model simulated CH_4 emission variability does not produce strong correlation with the ENSO cycle (Cross-Chapter Box 5.2, Figure 2), although observation evidence is emerging for lower CH_4 emissions during El Niños and greater emissions during the La Niña (Pandey et al., 2017).

Trees in upland and wetland forests contribute to CH_4 emissions by abiotic production in the canopy, by the methanogenesis taking place in the stem, and by conducting CH_4 from soil into the atmosphere (Covey and

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Megonigal, 2019). There is emerging evidence of the important role of trees in transporting and conducting CH_4 from soils into the atmosphere especially in tropics (Pangala et al., 2017), whereas direct production of CH_4 by vegetation only has a minor contribution (*limited evidence, high agreement*) (Bruhn et al., 2012; Covey and Megonigal, 2019). The contribution of trees in transporting CH_4 may further widen the gap between the bottom-up and top-down estimates in the global budget, particularly needing a reassessment of emissions in the tropics and in forested wetlands of temperate and boreal regions (Pangala et al., 2017; Jeffrey et al., 2019; Welch et al., 2019; Sjögersten et al., 2020).

Microbial methane uptake by soil comprises up to 5% (30 Tg yr^{-1}) of the total CH_4 sink in 2008–2017 (Table 5.2). There is evidence from experimental and modelling studies of increasing soil microbial uptake due to increasing temperature (Yu et al., 2017), although evidence for decreasing CH_4 consumption, possibly linked to precipitation changes, also exist (Ni and Groffman, 2018). The estimate of global methane loss by microbial oxidation in upland soils has been lowered marginally by 4 Tg yr^{-1}, compared to 34 Tg yr^{-1} in AR5, for the period 2000–2009. Termites, an infraorder of insects (Isoptera) found in almost all landmasses, emitted about 9 Tg yr^{-1} of CH_4 in 2000–2009, and increased emissions from the insects and other anthropods are projected (Brune, 2018).

5.2.2.4 Ocean and Inland Water Emissions and Sinks

In AR5, the ocean CH_4 emissions were reported together with geological emissions summing up to 54 (33–75) Tg yr^{-1}. Coastal oceans, fjords and mud volcanos are major source of CH_4 in the marine environment, but CH_4 flux measurements are sparse. Saunois et al. (2020) estimate that the oceanic budget, including biogenic, geological and hydrate emissions from coastal and open ocean, is 6 (range 4–10) Tg yr^{-1} for the 2000s, which is in good agreement with an air-sea flux measurement-based estimate of 6–12 Tg yr^{-1} (Weber et al., 2019). When estuaries are included, the total oceanic budget is 9–22 Tg yr^{-1}, with a mean value of 13 Tg yr^{-1}. A recent synthesis suggests that CH_4 emissions from shallow coastal ecosystems, particularly from mangroves, can be as high as 5–6 Tg yr^{-1} (Al-Haj and Fulweiler, 2020). The reservoir emissions, including coastal wetlands and tidal flats, contribute up to 13 Tg yr^{-1} (Borges and Abril, 2011; Deemer et al., 2016). Methane seepage from the Arctic shelf, possibly triggered by the loss of geological storage due to warming and thawing of permafrost and hydrate decomposition, has a wide estimated range of 0.0–17 Tg yr^{-1} (Shakhova et al., 2010, 2014, 2017; Berchet et al., 2016); advanced eddy covariance measurements put the best estimate at just about 3 Tg yr^{-1} from the East Siberian Arctic shelf (Thornton et al., 2020). The current flux is expected to be a mix of pre-industrial and climate change-driven fluxes, CH_4 seepage is anticipated to increase in a warmer world (Dean et al., 2018).

All geological sources around the world, including the coastal oceans and fjords, are estimated to emit CH_4 in the range of 35–76 Tg yr^{-1} (Etiope et al., 2019). There is evidence that the ventilation of geological CH_4 is *likely* to be smaller than 15 Tg yr^{-1} (Petrenko et al., 2017; Hmiel et al., 2020). A lower geological CH_4 ventilation will reduce the gap between bottom-up estimations and that are used in top-down models (Table 5.2), but widen the gap in the ratio of fossil-fuel derived sources to the biogenic sources for matching the $\Delta^{14}C$-CH_4 observations.

Inland water (lakes, rivers, streams, ponds, estuaries) emissions are proportionally the largest source of uncertainty in the CH_4 budget. Since AR5 (Ciais et al., 2013), the inland water CH_4 source has been revised from 8–73 Tg yr^{-1} (1980s) to 117–212 Tg yr^{-1} (2000s) with the availability of more observational data and improved areal estimates (Bastviken et al., 2011; Deemer et al., 2016; Stanley et al., 2016; DelSontro et al., 2018; Saunois et al., 2020). A large spatial and temporal variation in lake and river CH_4 fluxes (Wik et al., 2016; Crawford et al., 2017; Natchimuthu et al., 2017) and uncertainties in the global area of them (Allen and Pavelsky, 2018), together with a relatively small number of observations, varying measurement methods, for example those neglecting ebullition, varying upscaling methods and lack of appropriate process make the bottom-up CH_4 emission estimate uncertain (Sanches et al., 2019; Engram et al., 2020; Zhang et al., 2020a). Accordingly, there is no clear accounting of inland waters in top-down budgets, which is the main reason for the large gap in bottom-up and top-down estimates of "other sources" in the CH_4 budget (Table 5.2). Despite recent progress in separating wetlands from inland waters, there is double-counting in

ACCEPTED VERSION SUBJECT TO FINAL EDITS

the bottom-up estimates of their emissions (Thornton et al., 2016). Although there is evidence that regional human activities and warming both increase inland water CH_4 emissions (Beaulieu et al., 2019), the increase in the decadal emissions since AR5 (Ciais et al., 2013) rather reflect improvements in the estimate (*medium confidence)*, due to updates in the datasets and new upscaling approaches (Saunois et al., 2020).

5.2.2.5 CH_4 Budget

A summary of top-down and bottom-up estimations of CH_4 emissions and sinks for the period 2008–2017 is presented in Figure 5.14 (details in Table 5.2 and the associated text for the emissions). In addition to 483-682 Tg yr^{-1} loss of CH_4 in the troposphere by reaction with OH, 1–35 Tg yr^{-1} of CH_4 loss is estimated to occur in the lower troposphere due to Cl but are not included in the top-down models as shown in Table 5.2 (Hossaini et al., 2016; Gromov et al., 2018; Wang et al., 2019b). The decadal mean CH_4 burden/imbalance have increased at the rate of 30, 12, 7 and 21 Tg yr^{-1} in the 1980s (1980–1989), 1990s (1990–1999), 2000s (2000–2009) and the most recent decade (2008–2017), respectively (*virtually certain*), as can be estimated from observed atmospheric growth rate (Cross-Chapter Box 5.2, Figure 1).

Recent analysis using $\Delta^{14}C\text{-}CH_4$ in ice samples suggest that CH_4 emissions from fossil fuels exploitation are responsible for 30% of total CH_4 emissions (Lassey et al., 2007; Hmiel et al., 2020), which is largely inconsistent with sectorial budgets where fossil fuel emissions add up to 20% only (Ciais et al., 2013). However, recent model simulations produce fairly consistent $\delta^{13}C\text{-}CH_4$ values and trends as observed in the atmospheric samples using 20% fossil fuel emission fraction (Ghosh et al., 2015; Warwick et al., 2016; Fujita et al., 2020; Strode et al., 2020). Further research is needed in order to clarify relative roles of CH_4 emissions from fossil fuel exploitation and freshwater components. A key challenge is to accommodate higher estimated emissions from these two components without a major increase in the sinks for explaining the carbon and hydrogen isotopes variabilities at the same time.

[START FIGURE 5.14 HERE]

Figure 5.14: Global methane (CH_4) budget (2008–2017). Values and data sources as in Table 5.2 (in $TgCH_4$). The atmospheric stock is calculated from mean CH_4 concentration, multiplying a factor of 2.75 ± 0.015 Tg ppb^{-1}, which accounts for the uncertainties in global mean CH_4 (Chandra et al., 2021). Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

[START CROSS-CHAPTER BOX 5.2]

Cross-Chapter Box 5.2: Drivers of atmospheric methane changes during 1980–2019

Contributors: Prabir K. Patra (Japan/India), Josep G. Canadell (Australia), Frank Dentener (EU, Netherlands), Xin Lan (USA), Vaishali Naik (USA)

The atmospheric methane (CH_4) growth rate has varied widely over the past three decades, and the causes of which have been extensively studied since AR5. The mean growth rate decreased from 15 ± 5 ppb yr^{-1} in the 1980s to 0.48 ± 3.2 ppb yr^{-1} during 2000–2006 (the so-called quasi-equilibrium phase) and returned to an average rate of 7.6 ± 2.7 ppb yr^{-1} in the past decade (2010–2019) (based on data in Figure 5.14). Atmospheric CH_4 grew faster (9.3 ± 2.4 ppb yr^{-1}) over the last six years (2014–2019) – a period with prolonged El Niño conditions, which contributed to high CH_4 growth rates consistent with behaviour during previous El Niño events (Figure 5.14b). Because of large uncertainties in both the emissions and sinks of CH_4, it has been challenging to quantify accurately the methane budget and ascribe reasons for the growth over 1980-2019. In the context of CH_4 emissions mitigation, it is critical to understand if the changes in growth rates are caused by emissions from human activities or by natural processes responding to changing

ACCEPTED VERSION SUBJECT TO FINAL EDITS

climate. If CH_4 continues to grow at rates similar to those observed over the past decade, it will contribute to decadal scale climate change and hinder the achievement of the long-term temperature goals of the Paris Agreement (Nisbet et al., 2019)(7.3.2.2).

Cross-Chapter Box 5.2 Figure 1 shows the decadal CH_4 budget derived from the Global Carbon Project (GCP)-CH_4 synthesis for 1980s, 1990s and 2000s (Kirschke et al., 2013), and for 2010–2017 (Saunois et al., 2020). The imbalance of the sources and sinks estimated by atmospheric inversions (red bars) can be used to explain the changes in CH_4 concentration increase rates between the decades (Table 5.2).

[START CROSS-CHAPTER BOX 5.2, FIGURE 1 HERE]

Cross-Chapter Box 5.2, Figure 1: **Methane sources and sinks for four decades from atmospheric inversions with the budget imbalance** (source-sink; red bars) (plotted on the left y-axis). Top-down analysis from (Kirschke et al., 2013; Saunois et al., 2020), The global CH_4 concentration seen in the black line (plotted on the right y-axis), representing NOAA observed global monthly mean atmospheric CH_4 in dry-air mole fractions for 1983–2019 (Chapter 2, Annex III. Natural sources include emissions from natural wetlands, lakes and rivers, geological sources, wild animals, termites, wildfires, permafrost soils, and oceans. Anthropogenic sources include emissions from enteric fermentation and manure, landfills, waste and wastewater, rice cultivation, coal mining, oil and gas industry, biomass and biofuel burning. The top-down total sink is determined from global mass balance includes chemical losses due to reactions with hydroxyl (OH), atomic chlorine (Cl), and excited atomic oxygen (O^1D), and oxidation by bacteria in aerobic soils (Table 5.2). Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

[END CROSS-CHAPTER BOX 5.2, FIGURE 1 HERE]

Since AR5, many studies have discussed the role of different source categories in explaining the increase in CH_4 growth rate since 2007 and a coincident decrease of $\delta^{13}C$–CH_4 and δD–CH_4 isotopes (ref. Figure 5.13; Rice et al., 2016). Both ^{13}C and D are enriched in mass-weighted average source signatures for CH_4 emissions from thermogenic sources (e.g. coal mining, oil and gas industry) and pyrogenic (biomass burning) sources, and depleted in biogenic (e.g. wetlands, rice paddies, enteric fermentation, landfill and waste) sources. Proposed hypotheses for CH_4 growth (2007–2017) are inconclusive and vary from a concurrent decrease in thermogenic and increase in wetland and other biogenic emissions (Nisbet et al., 2016; Schwietzke et al., 2016), increase in from emissions agriculture in the tropics (Schaefer et al., 2016), a concurrent reduction in pyrogenic and increase in thermogenic emissions (Worden et al., 2017), or emission increase from biogenic sources and a slower increase in emissions from thermogenic sources compared to inventory emissions (Patra et al., 2016; Thompson et al., 2018; Jackson et al., 2020; Chandra et al., 2021).

A few studies have emphasised the role of chemical destruction by OH, the primary sink of methane, in driving changes in the growth of atmospheric methane abundance, in particular after 2006 (Rigby et al., 2017; Turner et al., 2017). Studies applying three-dimensional atmospheric inversion (McNorton et al., 2018), simple multi-species inversion (Thompson et al., 2018), as well as empirical method using a variety of observational constraints based on OH chemistry (Nicely et al., 2018; Patra et al., 2021), do not find trends in OH large enough to explain the methane changes post-2006. On the contrary, global chemistry-climate models based on fundamental principles of atmospheric chemistry and known emission trends of anthropogenic non-methane SLCFs simulate an increase in OH over this period (Zhao et al., 2019; Stevenson et al., 2020) (see Section 6.2.3). These contrasting lines of evidence suggest that OH changes may have had a small moderating influence on methane growth since 2007 (*low confidence*).

Cross-Chapter Box 5.2 Figure 2 shows that modelled wetland emission anomalies for all regions did not exhibit statistically significant trends (*high agreement between models, medium evidence*). Thus, the inter-decadal difference of total CH_4 emissions derived from inversion models and wetland emissions, arises

ACCEPTED VERSION SUBJECT TO FINAL EDITS

mainly from anthropogenic activities. The timeseries of regional emissions suggest that progress towards atmospheric CH_4 quasi-equilibrium was primarily driven by reductions in anthropogenic (fossil fuel exploitation) emissions in Europe, Russia and temperate North America over 1988–2000. In the global totals, emissions equalled loss in the early 2000s. The growth since 2007 is driven by increasing agricultural emissions from East Asia (1997–2017), West Asia (2005–2017), Brazil (1988–2017) and Northern Africa (2005–2017), and fossil fuel exploitations in temperate North America (2010–2017) (Lan et al., 2019; Crippa et al., 2020; Höglund-Isaksson et al., 2020; Jackson et al., 2020; Chandra et al., 2021).

[START CROSS-CHAPTER BOX 5.2, FIGURE 2 HERE]

Cross-Chapter Box 5.2, Figure 2: Anomalies in global and regional methane (CH_4) emissions for 1988–2017. Map in the centre shows mean CH_4 emission for 2010–2016. Multi-model mean (line) and 1-σ standard deviations (shaded) for 2000–2017 are shown for 9 surface CH_4 and 10 satellite XCH_4 inversions, and 22 wetland models or model variants that participated in GCP-CH_4 budget assessment (Saunois et al., 2020). The results for the period before 2000 are available from two inversions, 1) using 19 sites (Chandra et al., 2021; also used for the 2010-2016 mean emission map) and for global totals (Bousquet et al., 2006). The long-term mean values for 2010-2016 (common for all GCP–CH_4 inversions), as indicated within each panel separately, is subtracted from the annual-mean time series for the calculation of anomalies for each region. Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

[END CROSS-CHAPTER BOX 5.2, FIGURE 2 HERE]

Evidence from emission inventories at country level and regional scale inverse modelling that CH_4 growth rate variability during the 1988 through 2017 is closely linked to anthropogenic activities (*medium agreement*). Isotopic composition observations and inventory data suggest that concurrent emission changes from both fossil fuels and agriculture are playing roles in the resumed CH_4 growth since 2007 (*high confidence*). Shorter-term decadal variability is predominantly driven by the influence of El Niño Southern Oscillation on emissions from wetlands and biomass burning (Cross-Chapter Box 5.2 Figure 2), and loss due to OH variations (*medium confidence*), but lacking quantitative contribution from each of the sectors. By synthesising all available information regionally from a-priori (bottom-up) emissions, satellite and surface observations, including isotopic information, and inverse modelling (top-down), the capacity to track and explain changes in and drivers of natural and anthropogenic CH_4 regional and global emissions has been improved since the AR5, but fundamental uncertainties related to OH variations remain unchanged.

[END CROSS-CHAPTER BOX 5.2]

5.2.3 N_2O: Trends, Variability and Budget

In natural ecosystems, nitrous oxide (N_2O) is primarily produced as a by-product during the remineralisation of organic matter via the primary processes of nitrification and denitrification (Butterbach-Bahl et al., 2013; Voss et al., 2013). The net N_2O production is highly sensitive to local environmental conditions such as temperature, oxygen concentrations, pH and the concentrations of ammonium and nitrate, amongst others, causing strong variability of N_2O emissions in time and space even at small scales. Changes in the atmospheric abundance of N_2O result largely from the balance of the net N_2O sources on land and ocean, and the photochemical destruction of N_2O in the stratosphere.

Since AR5 (WGI, 6.4.3), improved understanding of N_2O sources allows for a more comprehensive assessement of the global N_2O budget (Table 5.3). This progress is based on extended atmospheric observations (Francey et al., 2003; Elkins et al., 2018; Prinn et al., 2018), improved atmospheric N_2O inversions (Saikawa et al., 2014; Thompson et al., 2019), updated and expanded inventories of N_2O sources

ACCEPTED VERSION SUBJECT TO FINAL EDITS

(Janssens-Maenhout et al., 2017; Winiwarter et al., 2018), as well as improved bottom-up estimate of freshwater, ocean and terrestrial sources (Martinez-Rey et al., 2015; Landolfi et al., 2017; Buitenhuis et al., 2018a; Lauerwald et al., 2019; Maavara et al., 2019; Tian et al., 2019).

The human perturbation of the natural nitrogen cycle through the use of synthetic fertilisers and manure, as well as nitrogen deposition resulting from land-based agriculture and fossil fuel burning has been the largest driver of the increase in atmospheric N_2O of 31.0 ± 0.5 parts per billion (ppb) (10%) between 1980 and 2019 (*robust evidence, high agreement*) (Tian et al., 2020). The long atmospheric lifetime of N_2O implies that it will take more than a century before atmospheric abundances stabilise after the stabilisation of global emissions. The rise of atmospheric N_2O is of concern, not only because of its contribution to the anthropogenic radiative forcing (see Chapter 7), but also because of the importance of N_2O in stratospheric ozone loss (Ravishankara et al., 2009; Fleming et al., 2011; Wang et al., 2014a).

5.2.3.1 Atmosphere

The tropospheric abundance of N_2O was 332.1 ± 0.4 ppb in 2019 (Figure 5.15), which is 23% higher than pre-industrial levels of 270.1 ± 6.0 ppb (*robust evidence, high agreement*). Current estimates are based on atmospheric measurements with high accuracy and density (Francey et al., 2003; Elkins et al., 2018; Prinn et al., 2018), and pre-industrial estimates are based on multiple ice-core records (see Section 2.2.3.2.3). The average annual tropospheric growth rate was 0.85 ± 0.03 ppb yr^{-1} during the period 1995 to 2019 (Figure 5.15a). The atmospheric growth rate increased by about 20% between the decade of 2000 to 2009 and the most recent decade of 2010 to 2019 (0.95 ± 0.04 ppb yr^{-1}) (*robust evidence, high agreement*). The growth rate in 2010–2019 was also higher than during 1970–2000 (0.6–0.8 ppb yr^{-1} (Ishijima et al., 2007)) and the thirty-year period prior to 2011 (0.73 ± 0.03 ppb yr^{-1}), as reported by AR5. New evidence since AR5 (WGI, 6.4.3) confirms that in the tropics and sub-tropics, large inter-annual variations in the atmospheric growth rate are negatively correlated with the multivariate ENSO index (MEI) and associated anomalies in land and ocean fluxes (Ji et al., 2019; Thompson et al., 2019; Yang et al., 2020c) (Figure 5.15a).

As assessed by SRCCL (IPCC, 2019a), combined firn, ice, air and atmospheric measurements show that the $^{15}N/^{14}N$ isotope ratio (*robust evidence, high agreement*) as well as the predominant position of the ^{15}N atom in atmospheric N_2O (*limited evidence, low agreement*) in N_2O has changed since 1940 (Figure 5.15b, c) whereas they were relatively constant in the pre-industrial period (Ishijima et al., 2007; Park et al., 2012; Prokopiou et al., 2017, 2018). SRCCL concluded that this change indicates a shift in the nitrogen-substrate available for de-nitrification, and the relative contribution of nitrification to the global N_2O source (*robust evidence, high agreement*), which are associated with increased fertiliser use in agriculture (Park et al., 2012; Snider et al., 2015; Prokopiou et al., 2018).

Since AR5 (WGI, 6.4.3), the mean atmospheric lifetime of N_2O has been revised to 116 ± 9 years (Prather et al., 2015). The small negative feedback of the N_2O lifetime to increasing atmospheric N_2O results in a slightly lower residence time (109 ± 10 years) of N_2O perturbations compared with that assessed by AR5 (118–131 years) (Prather et al., 2015). The dominant N_2O loss occurs through photolysis and oxidation by O(1D) radicals in the Stratosphere and amounts to approximately 13.1 (12.4–13.6) TgN yr^{-1} (Minschwaner et al., 1993; Prather et al., 2015; Tian et al., 2020).

[START FIGURE 5.15 HERE]

Figure 5.15: Changes in atmospheric nitrous oxide (N_2O) and its isotopic composition since 1940. (a) Atmospheric N_2O abundance (parts per billion, ppb) and growth rate (ppb yr^{-1}), (b) $\delta^{15}N$ of atmospheric N_2O, and (c) alpha-site ^{15}N–N_2O. Estimate are based on direct atmospheric measurements in the AGAGE , CSIRO, and NOAA networks (Prinn et al., 2000, 2018; Francey et al., 2003; Hall et al., 2007; Elkins et al., 2018), archived air samples from Cape Grim, Australia (Park et al., 2012), and firn air from NGRIP Greenland and H72 Antarctica (Ishijima et al., 2007), Law Dome Antarctica (Park et al., 2012), as well as a collection of firn ice samples from Greenland (Prokopiou et al., 2017, 2018). Shading in (a) is based on the multivariate ENSO index, with red indicating El Niño conditions (Wolter and Timlin, 1998). Further

ACCEPTED VERSION SUBJECT TO FINAL EDITS

details on data sources and processing are available in the chapter data table (Table 5.SM.6).

[END FIGURE 5.15 HERE]

5.2.3.2 Anthropogenic N_2O Emissions

AR5 (WGI, 6.4.3) and SRCCL (2.3.3) concluded that agriculture is the largest anthropogenic source of N_2O emissions. Since SRCCL (2.3.3), a new synthesis of inventory-based and modelling studies shows that the widespread use of synthetic fertilisers and manure on cropland and pasture, manure management and aquaculture resulted in 3.8 (2.5–5.8) TgN yr^{-1} (average 2007–2016) (*robust evidence, high agreement*) (Table 5.3) (Winiwarter et al., 2018; FAO, 2019; Janssens-Maenhout et al., 2019; Tian et al., 2020). Observations from field-measurements (Song et al., 2018), inventories (Wang et al., 2020) and atmospheric inversions (Thompson et al., 2019) further corroborate the assessment of the SRCCL that there is a non-linear relationship between N_2O emissions and nitrogen input, implying an increasing fraction of fertiliser lost as N_2O with larger fertiliser excess (*medium evidence, high agreement*). Several studies using complementary methods indicate that agricultural N_2O emissions have increased by more than 45% since the 1980s (*high confidence*) (Davidson, 2009; Janssens-Maenhout et al., 2017; Winiwarter et al., 2018; Tian et al., 2020) (Figure 5.16, Table 5.3), mainly due to the increased use of nitrogen fertiliser and manure. N_2O emissions from aquaculture are amongst the fastest rising contributors of N_2O emissions, but their overall magnitude is still small in the overall N_2O budget (Tian et al., 2020).

[START FIGURE 5.16 HERE]

Figure 5.16: Decadal mean nitrous oxide (N_2O) emissions for 2007–2016 and its change since 1850 based on process-model projections. The total effect including that from anthropogenic nitrogen additions (atmospheric deposition, manure addition, fertiliser use and land-use) is evaluated against the background flux driven by changes in atmospheric CO_2 concentration, and climate change. Fluxes are derived from the N_2O Model Intercomparison Project ensemble of terrestrial biosphere models (Tian et al., 2019) and three ocean biogeochemical models (Landolfi et al., 2017; Battaglia and Joos, 2018a; Buitenhuis et al., 2018b). Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

[END FIGURE 5.16 HERE]

The principal non-agricultural anthropogenic sources of N_2O are industry, specifically chemical processing, wastewater, and the combustion of fossil fuels (Table 5.3). Industrial emissions of N_2O mainly due to nitric and adipic acid production have decreased in North America and Europe since the wide-spread installation of abatement technologies in the 1990s (Pérez-Ramírez et al., 2003; Lee et al., 2011; Janssens-Maenhout et al., 2019). There is still considerable uncertainty in industrial emissions from other regions of the world with contrasting trends between inventories (Thompson et al., 2019). Globally, industrial emissions and emissions from fossil fuel combustion by stationary sources, such as power plants, as well as smaller emissions from mobile sources (e.g. road transport and aviation) have remained nearly constant between1980s and 2007-2016 (*moderate evidence, medium agreement*) (Janssens-Maenhout et al., 2017; Winiwarter et al., 2018; Tian et al., 2020). Wastewater N_2O emissions, including those from domestic and industrial sources have increased from 0.2 (0.1–0.3) TgN yr^{-1} to 0.35 (0.2–0.5) TgN yr^{-1} between the 1980s and 2007–2016 (Tian et al., 2020).

Biomass burning from crop residue burning, grassland, savannah and forest fires, as well as biomass burnt in household stoves, releases N_2O during the combustion of organic matter. Updated inventories since AR5 (WGI, 6.4.3) result in a lower range of the decadal mean emissions of 0.6 (0.5–0.8) TgN yr^{-1} (van der Werf et al., 2017; Tian et al., 2020). The attribution of grassland, savannah or forest fires to natural or anthropogenic origins is uncertain, preventing a separation of the biomass burning source into natural and anthropogenic.

ACCEPTED VERSION SUBJECT TO FINAL EDITS

5.2.3.3 Emissions from Ocean, Inland Water Bodies and Estuaries

Since AR5 (WGI, 6.4.3), new estimates of the global ocean N_2O source derived from ocean biogeochemistry models are 3.4 (2.5–4.3) TgN yr^{-1} for the period 2007-2016 (Manizza et al., 2012; Suntharalingam et al., 2012; Martinez-Rey et al., 2015; Landolfi et al., 2017; Buitenhuis et al., 2018a; Tian et al., 2020) (Figure 5.16). This is slightly lower than climatological estimates from empirically based-methods and surface ocean data syntheses (Bianchi et al., 2012; Yang et al., 2020c). Nitrous oxide processes in coastal upwelling zones continue to be poorly represented in global estimates of marine N_2O emissions (Kock et al., 2016), but may account for an additional 0.2 to 0.6 TgN yr^{-1} of the global ocean source (Seitzinger et al., 2000; Nevison et al., 2004).

In the oxic ocean (> 97% of ocean volume), nitrification is believed to be the primary N_2O source (Freing et al., 2012). In sub-oxic ocean zones (see Section 5.3), where denitrification prevails, higher N_2O yields and turnover rates make these regions potentially significant sources of N_2O (Arévalo-Martínez et al., 2015; Babbin et al., 2015; Ji et al., 2015). The relative proportion of ocean N_2O from oxygen-minimum zones is highly uncertain (Zamora et al., 2012). Estimates derived from in situ sampling, particularly in the eastern tropical Pacific, suggest significant fluxes from these regions, and potentially accounting for up to 50% of the global ocean source (Codispoti, 2010; Arévalo-Martínez et al., 2015; Babbin et al., 2015). However, recent global-scale analyses estimate lower contributions (4 to 7%, Battaglia and Joos, 2018; Buitenhuis et al., 2018). Further investigation is required to reconcile these estimates and provide improved constraints on the N_2O source from low-oxygen zones.

Atmospheric deposition of anthropogenic N on oceans can stimulate marine productivity and influence ocean emissions of N_2O. New ocean model analyses since AR5 (WGI, 6.4.3), suggest a relatively modest global potential impact of 0.01–0.32 TgN yr^{-1} (pre-industrial to present-day) equivalent to 0.5–3.3% of the global ocean N_2O source (Suntharalingam et al., 2012; Jickells et al., 2017; Landolfi et al., 2017). However, larger proportionate impacts are predicted in nitrogen-limited coastal and inland waters down-wind of continental pollution outflow, such as the Northern Indian Ocean (Jickells et al., 2017; Suntharalingam et al., 2019).

Inland waters and estuaries are generally sources of N_2O as a result of nitrification and denitrification of dissolved inorganic nitrogen, however, they can serve as N_2O sinks in specific conditions (Webb et al., 2019). Since AR5 (WGI, 6.4.3), improved emission factors including their spatio-temporal scaling, and consideration of transport within the aquatic system allow to better constrain these emissions (Murray et al., 2015; Hu et al., 2016; Lauerwald et al., 2019; Maavara et al., 2019; Kortelainen et al., 2020; Yao et al., 2020). Despite uncertainties because of the side-effects of canals and reservoirs on nutrient cycling, these advances permit to attribute a fraction of inland water N_2O emissions to anthropogenic sources (Tian et al., 2020), which contributes to the increased anthropogenic share of the global N_2O source in this report compared to AR5 (Ciais et al., 2013). As indirect consequence of agricultural nitrogen-use and waste-water treatment, the anthropogenic emissions from inland waters have increased by about a quarter (0.1 TgN yr^{-1}) between the 1980s and 2007–2016 (Tian et al., 2020).

5.2.3.4 Emissions and Sinks in Non-Agricultural Land

Soils are the largest natural source of N_2O, arising primarily from nitrogen processing associated with microbial nitrification and denitrification (Butterbach-Bahl et al., 2013; Snider et al., 2015) (Table 5.3). Under some conditions, soils can also act as a net sink of N_2O, but this effect is small compared to the overall source (Schlesinger, 2013). Since AR5 (WGI, 6.4.3), improved global process-based models (Tian et al., 2019) suggest a present-day source of 6.7 (5.3–8.1) TgN yr^{-1} (2007–2016 average), which is consistent with the estimate in AR5. Process-based models and inventory-based methods show that increased N deposition has enhanced terrestrial N_2O emissions by 0.8 (0.4–1.4 TgN yr^{-1}) relative to approximately pre-industrial times, and by 0.2 (0.1–0.2) TgN yr^{-1} between the 1980s and 2007–2016 (*limited evidence, medium agreement*) (Figure 5.16) (Tian et al., 2019). This estimate is at the high end of the range reported in AR5 (WGI, 6.4.3). Model projections further show that global warming has led to increased soil N_2O emissions of

ACCEPTED VERSION SUBJECT TO FINAL EDITS

0.8 (0.3–1.3) TgN yr^{-1} since approximately pre-industrial times, of which about half occurred since the 1980s (*limited evidence, high agreement)* (Tian et al., 2019, 2020).

SRCCL assessed that deforestation and other forms of land-use change significantly alter terrestrial N_2O emissions through emission pulses following conversions, resulting generally in long-term reduced emissions in unfertilised ecosystems (*medium evidence, high agreement*). This conclusion is supported by a recent study demonstrating that the deforestation-pulse effect is offset by the effect of reduced area of mature tropical forests (Tian et al., 2020).

Uncertainties remain in process-based models with respect to their ability to capture the complicated responses of terrestrial N_2O emissions to rain pulses, freeze-thaw cycles and the net consequences of elevated levels of CO_2 accurately (Tian et al., 2019). Emerging literature suggests that permafrost thaw may contribute significantly to arctic N_2O emissions (Voigt et al., 2020), but these processes are not yet adequately represented in models and upscaling to large-scale remains a significant challenge.

5.2.3.5 N_2O budget

[START FIGURE 5.17 HERE]

Figure 5.17: Global nitrous oxide (N_2O) budget (2007–2016). Values and data sources as in Table 5.3. The atmospheric stock is calculated from mean N_2O concentration, multiplying a factor of 4.79 ± 0.05 Tg ppb^{-1} (Prather et al., 2012). Pool sizes for the other reservoirs are largely unknown. Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

[END FIGURE 5.17 HERE]

The synthesis of bottom-up estimates of N_2O sources (Sections 5.2.3.2–5.2.3.4; Figure 5.17) yields a global source of 17.0 (12.2–23.5) TgN yr^{-1} for the years 2007–2016 (Table 5.3). This estimate is comparable to AR5, but the uncertainty range has been reduced primarily due to improved estimates of ocean and anthropogenic N_2O sources. Since AR5 (WGI, 6.4.3), improved capacity to estimate N_2O sources from atmospheric N_2O measurements by inverting models of atmospheric transport provides a new and independent constraint for the global N_2O budget (Saikawa et al., 2014; Thompson et al., 2019; Tian et al., 2020). The decadal mean source derived from these inversions is remarkably consistent with the bottom-up global N_2O budget for the same period, however, the split between land and ocean sources based on atmospheric inversions is less well constrained, yielding a smaller land source of 11.3 (10.2–13.2) TgN yr^{-1} and a larger ocean source of 5.7 (3.4–7.2) TgN yr^{-1}, respectively, compared to bottom-up estimates.

Supported by multiple studies and extensive observational evidence (Sections 5.2.3.2–5.2.3.4; Figure 5.17), anthropogenic emissions contributed about 40% (7.3; uncertainty range: 4.2–11.4 TgN yr^{-1}) to the total N_2O source in 2007–2016 (*high confidence)*. This estimate is larger than in AR5 (WGI, 6.4.3) due to a larger estimated effect of nitrogen deposition on soil N_2O emission and the explicit consideration of the role of anthropogenic nitrogen in determining inland water and estuary emissions.

Based on bottom-up estimates, anthropogenic emissions from agricultural nitrogen use, industry and other indirect effects have increased by 1.7 (1.0–2.7) TgN yr^{-1} between the decades 1980–1989 and 2007–2016, and are the primary cause of the increase in the total N_2O source (*high confidence)*. Atmospheric inversions indicate that changes in surface emissions rather than in the atmospheric transport or sink of N_2O are the cause for the increased atmospheric growth rate of N_2O (*robust evidence, high agreement*) (Thompson et al., 2019). However, the increase of 1.6 (1.4–1.7) TgN yr^{-1} in global emissions between 2000–2005 and 2010–2015 based on atmospheric inversions is somewhat larger than bottom-up estimates over the same period, primarily because of differences in the estimates of land-based emissions.

ACCEPTED VERSION SUBJECT TO FINAL EDITS

[START TABLE 5.3 HERE]

Table 5.3: Global N_2O budget (units TgN yr^{-1}) averaged over the 1980s, 1990s, 2000s as well as the recent decade starting in 2007. Uncertainties represent the assessed range of source/sink estimates. All numbers are reproduced from (Tian et al., 2020) based on a compilation of inventories, bottom-up models, as well as atmospheric inversions. For detailed information on datasets, see Data Table 5.SM.6.

5.2.4 The Relative Importance of CO2, CH4, and N2O

The total influence of anthropogenic greenhouse gases (GHGs) on the Earth's radiative balance is driven by the combined effect of those gases, and the three most important were discussed separately in the previous sections. This section compares the balance of the sources and sinks of these three gases and their regional net flux contributions to the radiative forcing. CO_2 has multiple residence times in the atmosphere from one year to many thousands of years (Box 6.1 in Ciais et al. (2013)), and N_2O has a mean lifetime of 116 years. They are both long-lived GHGs, while CH_4 has a lifetime of 9.0 years and is considered a short-lived GHGs (see Chapter 2 for lifetime of GHGs, Chapter 6 for CH_4 chemical lifetime, and Chapter 7 for effective radiative forcing of all GHGs).

Figure 5.18 shows the contribution to radiative forcing of CO_2, CH_4, N_2O, and the halogenated species since the 1900s and the more recent decades. For the period 1960–2019, the relative contribution to the total effective radiative forcing (ERF) was 63% for CO_2, 11% for CH_4, 6% for N_2O, and 17% for the halogenated species (Chapter 7; Figure 5.18). The systematic decline in the relative contribution to ERF for CH_4 since 1850 is caused by slower increase rate of CH_4 in the recent decades, at 6, 10 and 5 ppb yr^{-1} during 1850-2019, 1960–2019 and 2000–2019, respectively, in comparison with the increasing rate of CO_2 (at 0.7, 1.6 and 2.2 ppm yr^{-1}, respectively) and N_2O (at 0.4, 0.7 and 0.9 ppb yr^{-1}, respectively) (Figure 5.4). Owing to the shorter lifetime of CH_4, the effect of reduction in emission increase rate on the ERF increase is evident at inter-decadal timescales.

[START FIGURE 5.18 HERE]

Figure 5.18: Contributions of carbon dioxide (CO_2), methane (CH_4), nitrous oxide (N_2O) and halogenated species to the total effective radiative forcing (ERF) increase since 1850 and 1960, and for 2000 to 2009. ERF data are taken from Annex III (based on calculations from Chapter 7). Note that the sum of the ERFs exceeds 100% because there are negative ERFs due to aerosols and clouds. Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

[END FIGURE 5.18 HERE]

Atmospheric abundance of GHGs is proportional to their emissions-loss budgets in the Earth's environment. There are multiple metrics to evaluate the relative importance of different GHGs for the global atmospheric radiation budget and the socioeconomic impacts (Section 7.6). Metrics for weighting emissions are further developed in the AR6 of IPCC WGIII. Figure 5.19 shows the regional emissions of the three main GHGs. For East Asia, Europe, Temperate North America and West Asia, the most dominant GHG source is CO_2 (*high confidence*) (Figure 5.19), while for East Asia, South Asia, Southeast Asia, Tropical South America, Temperate North America and Central Africa is CH_4 (Figure 5.19). The N_2O emissions are dominant in regions with intense use of nitrogen fertilisers in agriculture. Only boreal North America showed net sinks of CO_2, while close to flux neutrality is observed for North Asia, Southern Africa, and Australasia. Persistent emission of CO_2 is observed for Tropical and South America, northern Africa, and southeast Asia (*medium confidence*). The *medium confidence* arises from large uncertainties in the estimated non-fossil fuel CO_2 fluxes over these regions due to the lack of high-quality atmospheric measurements.

[START FIGURE 5.19 HERE]

Figure 5.19: Regional distributions of net fluxes of carbon dioxide (CO_2), methane (CH_4), nitrous oxide (N_2O) on the Earth's surface. The region divisions, shown as the shaded map, are made based on ecoclimatic characteristics of the land. The fluxes include those from anthropogenic activities and natural causes that result from responses to anthropogenic greenhouse gases and climate change (feedbacks) as in the three budgets shown in Sections 5.2.1.5, 5.2.2.5, and 5.2.3.5. The CH_4 and N_2O emissions are weighted by

ACCEPTED VERSION SUBJECT TO FINAL EDITS

arbitrary factors of 50 and 500, respectively, for depiction by common y-axes. Fluxes are shown as the mean of the inverse models as available from (Thompson et al., 2019; Friedlingstein et al., 2020; Saunois et al., 2020). Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

[END FIGURE 5.19 HERE]

5.3 Ocean Acidification and Deoxygenation

The surface ocean has absorbed a quarter of all anthropogenic CO_2 emissions mainly through physical-chemical processes (McKinley et al., 2016; Gruber et al., 2019b; Friedlingstein et al., 2020). Once dissolved in seawater, CO_2 reacts with water and forms carbonic acid. In turn carbonic acid dissociates, leading to a decrease in the concentration of carbonate (CO_3^{-2}) ions, and increasing both bicarbonate (HCO_3^-) and hydrogen (H^+) ion concentration, which has caused a shift in the carbonate chemistry towards a less basic state, commonly referred to as ocean acidification (Caldeira and Wickett, 2003; Orr et al., 2005; Doney et al., 2009). Although the societal concern for this problem is relatively recent (about the last 20 years), the physical-chemical basis for the ocean absorption (sink) of atmospheric CO_2 has been discussed much earlier by Revelle and Suess (1957). The AR5 and SROCC assessments were of *robust evidence* that the H^+ ion concentration is increasing in the surface ocean, thereby reducing seawater pH (= - log[H^+]) (Orr et al., 2005; Feely et al., 2009; Ciais et al., 2013; Bindoff et al., 2019; Chapter 2, Section 2.3.4.1), and there is *high confidence* that ocean acidification is impacting marine organisms (Bindoff et al., 2019).

Ocean oxygen decline, or deoxygenation, is driven by changes in ocean ventilation and solubility (Bindoff et al., 2019). It is *virtually certain* that anthropogenic forcing has made a substantial contribution to the ocean heat content increase over the historical period (Bindoff et al., 2019; IPCC, 2019c) (Chapter 9, Section 2.3.3.1), strengthening upper water column stratification. Ocean warming decreases the solubility of dissolved oxygen in seawater, and it contributes to about 15% of the dissolved oxygen decrease in the oceans according to estimates based on solubility and the recent SROCC assessment (*medium confidence*), especially in sub-surface waters, between 100–600 m depth (Helm et al., 2011; Schmidtko et al., 2017; Breitburg et al., 2018; Oschlies et al., 2018) (SROCC, Section 5.3.1). Stratification reduces the ventilation flux into the ocean interior, contributing to most of the remaining ocean deoxygenation (Schmidtko et al., 2017; Breitburg et al., 2018) (Section 3.6.2). Deoxygenation may enhance the emissions of nitrous oxide, especially from oxygen minimum zones (OMZs) or hypoxic coastal areas (Breitburg et al., 2018; Oschlies et al., 2018). Since SROCC (Bindoff et al., 2019), CMIP6 model simulation results agree with the reported 2% loss (4.8 ± 2.1 Pmoles O_2) in total dissolved oxygen in the upper ocean layer (100–600 m) for the 1970–2010 period (Helm et al., 2011; Ito et al., 2017; Schmidtko et al., 2017; Kwiatkowski et al., 2020) (Section 2.3.4.2). The response of marine organisms to the coupled effects of ocean warming, acidification and deoxygenation occur at different metabolic levels on different groups, and include respiratory stress and reduction of thermal tolerance by organisms (Gruber, 2011; Bindoff et al., 2019; IPCC, 2019c; Kawahata et al., 2019). An assessment of these effects on marine biota is found in WGII AR6 Chapter 2.

This section assesses past events of ocean acidification and deoxygenation (Section 5.3.1), the historical trends and spatial variability for the upper ocean (Section 5.3.2) and the ocean interior (Section 5.3.3). Future projections for ocean acidification and the drivers in the coastal ocean are assessed in Sections 5.3.4 and 5.3.5, respectively.

5.3.1 Paleoclimate Context

5.3.1.1 Paleocene-Eocene Thermal Maximum

The Paleocene-Eocene thermal maximum (PETM) was an episode of global warming exceeding pre-industrial temperatures by 4°C–8°C (McInerney and Wing, 2011; Dunkley Jones et al., 2013) that occurred 55.9–55.7 Ma. The PETM involved a large pulse of geologic CO_2 released into the ocean-atmosphere

ACCEPTED VERSION SUBJECT TO FINAL EDITS

system in 3–20 kyr (Zeebe et al., 2016; Gutjahr et al., 2017; Kirtland Turner et al., 2017; Kirtland Turner, 2018; Gingerich, 2019) (5.2.1.1). In response to carbon emissions during the PETM, observationally-constrained model simulations report an increase in atmospheric CO_2 concentrations ranging from about 900 ppm to >2000 ppm (Gutjahr et al., 2017; Cui & Schubert, 2018; Anagnostou et al., 2020) (Chapter 2). The PETM thus provides a test for our understanding of the ocean's response to the increase in carbon (and heat) emissions over geologically short timescales.

A limited number of independent proxy records indicate that the PETM was associated with a surface ocean pH decline ranging from 0.15 to 0.30 units (Gutjahr et al., 2017; Penman et al., 2014; Babila et al., 2018). It was also accompanied by a rapid (<10 ka) shallowing of the carbonate saturation horizon, resulting in the widespread dissolution of sedimentary carbonate, followed by a gradual (100 kyr) recovery (Zachos et al., 2005; Bralower et al., 2018). The remarkable similarity among sedimentary records spanning a wide range of ecosystems suggests with *medium confidence* that the perturbation in the ocean carbonate saturation was global (Babila et al., 2018) and directly resulted from elevated atmospheric CO_2 levels. The degree of acidification is similar to the 0.4 pH unit decrease projected for the end of the 21st century under RCP8.5 (Gattuso et al., 2015) and is estimated to have occurred at a rate about one order of magnitude slower than the current rate of ocean acidification (Zeebe et al., 2016). There is *low confidence* in the inferred rates of ocean acidification inherent to the range of uncertainties affecting rates estimates based on marine sediments (Section 5.1.2.1).

Recent model outputs as well as globally distributed geochemical data reveal with *medium confidence* widespread ocean deoxygenation during the PETM (Dickson et al., 2012; Winguth et al., 2012; Dickson et al., 2014; Chang et al., 2018; Remmelzwaal et al., 2019), with parts of the ocean potentially becoming drastically oxygen-depleted (anoxic) (Yao et al., 2018; Clarkson et al., 2021). Deoxygenation affected the surface ocean globally (including the Arctic Ocean) (Sluijs et al., 2006), due to vertical and lateral expansion of Oxygen Minimum Zones (OMZs) (Zhou et al., 2014) that resulted from warming and related changes in ocean stratification. Expansion of OMZs may have stimulated N_2O production through water-column (de)nitrification (Junium et al., 2018). The degree to which N_2O production impacted PETM warming, however, has not yet been established.

The feedbacks associated with recovery from the PETM are uncertain, yet could include drawdown associated with silicate weathering (Zachos et al., 2005) and regrowth of terrestrial and marine organic carbon stocks (Bowen and Zachos, 2010; Gutjahr et al., 2017).

5.3.1.2 Last Deglacial Transition

The Last deglacial transition (LDT) is the best documented climatic transition in the past associated with a substantial atmospheric CO_2 rise ranging from 190 to 265 ppm between 18–11 ka (Marcott et al., 2014). The amplitude of the deglacial CO_2 rise is thus on the order of magnitude of the increase undergone since the industrial revolution.

Boron isotope ($\delta^{11}B$) data suggest a 0.15–0.05 unit decrease in sea-surface pH (Hönisch and Hemming, 2005; Henehan et al., 2013) across the LDT, an average rate of decline of about 0.002 units per century compared with the current rate of more than 0.1 units per century (Bopp et al., 2013; Gattuso et al., 2015). Planktonic foraminiferal shell weights decreased by 40% to 50% (Barker & Elderfield, 2002), and coccolith mass decreased by about 25% (Beaufort et al., 2011) across the LDT. Independent proxy reconstructions thus highlight with *high confidence* that pH values decreased as atmospheric CO_2 concentrations increased across the LDT. There is however *low confidence* in the inferred rate of ocean acidification owing to multiple sources of uncertainties affecting rates estimates based on marine sediments (Section 5.1.2.1). Geochemical and micropaleontological evidence suggest that intermediate-depth OMZs almost vanished during the LGM (Jaccard et al., 2014). However, multiple lines of evidence suggest with *medium confidence* that the deep (>1500 m) ocean became depleted in O_2 (concentrations were possibly lower than 50 µmol kg^{-1}) globally (Jaccard and Galbraith, 2012; Hoogakker et al., 2015, 2018, Gottschalk et al., 2016, 2020; Anderson et al., 2019) as a combined result of sluggish ventilation of the ocean subsurface (Gottschalk et al.,

ACCEPTED VERSION SUBJECT TO FINAL EDITS

2016, 2020; Skinner et al., 2017) and a generally more efficient marine biological carbon pump (Buchanan et al., 2016; Yamamoto et al., 2019; Galbraith and Skinner, 2020).

During the LDT, deep ocean ventilation increased as Antarctic bottom water (AABW) (Skinner et al., 2010; Gottschalk et al., 2016; Jaccard et al., 2016) and subsequently the Atlantic meridional overturning circulation (McManus et al., 2004; Lippold et al., 2016) resumed, transferring previously sequestered remineralised carbon from the ocean interior to the upper ocean and eventually the atmosphere (Skinner et al., 2010; Galbraith and Jaccard, 2015; Gottschalk et al., 2016; Ronge et al., 2016; Sikes et al., 2016; Rae et al., 2018; Ronge et al., 2020), contributing to the deglacial CO_2 rise. Intermediate depths lost oxygen as a result of sluggish ventilation and increasing temperatures (decreasing saturation) as the world emerged from the last Glacial period OMZs underwent a large volumetric increase at the beginning of the Bølling-Allerød (B/A), a northern-hemisphere wide warming event, 14.7 ka (Jaccard and Galbraith, 2012; Praetorius et al., 2015) with deleterious consequences for benthic ecosystems (e.g. Moffitt et al., 2015). These observations indicate with *high confidence* that the rate of warming, affecting the solubility of oxygen and upper water column stratification, coupled with changes in subsurface ocean ventilation impose a direct control on the degree of ocean deoxygenation, implying a high sensitivity of ocean oxygen loss to warming. The expansion of OMZs contributed to a widespread increase in water column (de)nitrification (Galbraith et al., 2013), which contributed substantially to enhanced marine N_2O emissions (Schilt et al., 2014; Fischer et al., 2019). Nitrogen stable isotope measurements on N_2O extracted from ice cores suggest that approximately one third (on the order of 0.7 ± 0.3 TgN yr^{-1}) of the deglacial increase in N_2O emissions relates to oceanic sources (Schilt et al., 2014; Fischer et al., 2019).

5.3.2 Historical Trends and Spatial Characteristics in the Upper Ocean

5.3.2.1 Reconstructed Centennial Ocean Acidification Trends

Ocean pH timeseries are are based on the reconstruction of coral boron isotope ratios ($\delta^{11}B$). A majority of coral $\delta^{11}B$ data have been generated from the western Pacific region with a few records from the Atlantic Ocean. Biweekly resolution paleo-pH records show monsoonal variation of about 0.5 pH unit in the South China Sea (Liu et al., 2014). Interannual ocean pH variability in the range of 0.07–0.16 pH unit characterises southwest Pacific corals that are attributed to ENSO (Wu et al., 2018a) and river runoff (D'Olivo et al., 2015). Decadal (10, 22 and 48-year) ocean pH variations in the southwest Pacific have been linked to the Interdecadal Pacific Oscillation, causing variations of up to 0.30 pH unit in the Great Barrier Reef (Pelejero et al., 2005; Wei et al., 2009) but weaker (about 0.08 pH unit) in the open ocean (Wu et al., 2018a). Decadal variations in the South China Sea ocean pH changes of 0.10–0.20 also have been associated with the variation in the East Asian monsoon (Liu et al., 2014; Wei et al., 2015), as a weakening of the Asian winter monsoon leads to sluggish water circulation within the reefs, building up localised CO_2 concentration in the water due to calcification and respiration.

Since the beginning of the industrial period in the mid-19th century, coral $\delta^{11}B$-derived ocean pH has decreased by 0.06–0.24 pH unit in the South China Sea (Liu et al., 2014; Wei et al., 2015) and 0.12 pH unit in the southwest Pacific (Wu et al., 2018a). Since the mid-20th century, a distinct feature of coral $\delta^{11}B$ records relates to ocean acidification trends, albeit having a wide-range of values: 0.12–0.40 pH unit in the great barrier reef (Wei et al., 2009; D'Olivo et al., 2015), 0.05–0.08 pH unit in the northwest Pacific (Shinjo et al., 2013) and 0.04–0.09 pH unit in the Atlantic Ocean (Goodkin et al., 2015; Fowell et al., 2018). Concurrent coral carbon isotopic ($\delta^{13}C$) measurements infer ocean uptake of anthropogenic CO_2 from the combustion of fossil fuel, based on the lower abundance of ^{13}C in fossil fuel carbon. Western Pacific coral records show depleted $\delta^{13}C$ trends since the late 19th century that are more prominent since the mid-20th century (*high confidence*) (Pelejero, 2005; Wei et al., 2009; Shinjo et al., 2013; Liu et al., 2014; Kubota et al., 2017; Wu et al., 2018).

Overall, many of the records show a highly variable seawater pH underlaying strong imprints of internal climate variability (*high confidence*), and in most instances superimposed on a decreasing $\delta^{11}B$ trend that is indicative of anthropogenic ocean acidification in recent decades (*medium confidence*). The robustness of

ACCEPTED VERSION SUBJECT TO FINAL EDITS

seawater pH reconstructions is currently limited by the uncertainty on the calibration of the $\delta^{11}B$ proxy in different tropical coral species.

5.3.2.2 Observations of Ocean Acidification over the Recent Decades

SROCC (Section 5.2.2.3) indicated it is *virtually certain* that the ocean has undergone acidification globally in response to ocean CO_2 uptake and concluded that pH in open ocean surface water has changed by a *virtually certain* range of –0.017 to –0.027 pH units per decade since the late 1980s. Since SROCC, continued observations of seawater carbonate chemistry at ocean time series stations and compiled shipboard studies providing temporally resolved and methodologically consistent datasets have further strengthened the evidence of the progress of acidification across all regions of the oceans (Jiang et al., 2019) (Figure 5.20; Supplementary Material Table 5.SM.3) (Section 2.3.3.5).

In the subtropical open oceans, decreases in pH have been reported with a *very likely* range of rate from –0.016 to –0.019 pH units per decade since 1980s, which equate to approximately 4 % increase in hydrogen ion concentration ($[H^+]$) per decade. Accordingly, the saturation state Ω ($=[Ca^{2+}][CO_3^{2-}]/K_{sp}$) of seawater with respect to calcium carbonate mineral aragonite has been declining at rates ranging from –0.07 to –0.12 per decade (González-Dávila et al., 2010; Feely et al., 2012; Bates et al., 2014; Takahashi et al., 2014; Ono et al., 2019; Bates and Johnson, 2020) (Supplementary Material Table 5.SM.3). These rates are consistent with the rates expected from the transient equilibration with increasing atmospheric CO_2 concentrations, but the variability of rate in decadal time-scale has also been detected with *robust evidence* (Ono et al., 2019; Bates and Johnson, 2020). In the tropical Pacific, its central and eastern upwelling zones exhibited a faster pH decline of –0.022 to –0.026 pH unit per decade due to increased upwelling of CO_2-rich sub-surface waters in addition to anthropogenic CO_2 uptake (Sutton et al., 2014; Lauvset et al., 2015). By contrast, warm pool in the western tropical Pacific exhibited slower pH decline of –0.010 to –0.013 pH unit per decade (Supplementary Material Table 5.SM.3) (Lauvset et al., 2015; Ishii et al., 2020). Observational and modeling studies (Nakano et al., 2015; Ishii et al., 2020) consistently suggest that slower acidification in this region is attributable to the anthropogenic CO_2 taken up in the extra-tropics around a decade ago and transported to the tropics via shallow meridional overturning circulations.

In open subpolar and polar zones, the *very likely* range (–0.003 to –0.026 pH unit per decade) and uncertainty (up to 0.010) observed in pH decline are larger than in the subtropics, reflecting the complex interplay between physical and biological forcing mechanisms (Olafsson et al., 2009; Midorikawa et al., 2012; Bates et al., 2014; Takahashi et al., 2014; Lauvset et al., 2015; Wakita et al., 2017). Nevertheless, the *high agreement* of pH decline among these available time-series studies leads to *high confidence* in the trend of acidification in these zones. In the Arctic Ocean, a temporally limited time series of carbonate chemistry measurements prevents drawing robust conclusions on ocean acidification trends. However, the carbonate saturation state Ω is generally low, and observational studies show with *robust evidence* that the recent extensive melting of sea ice leading to enhanced air-sea CO_2 exchange, large freshwater inputs, together with river discharge and glacial drainage, as well as the degradation of terrestrial organic matter in seawater, result in the decline of Ω of aragonite to undersaturation (Bates et al., 2009; Chierici and Fransson, 2009; Yamamoto-Kawai et al., 2009; Azetsu-Scott et al., 2010; Robbins et al., 2013; Fransson et al., 2015; Semiletov et al., 2016; Anderson et al., 2017; Qi et al., 2017; Zhang et al., 2020; Beaupré-Laperrière et al., 2020) (SROCC Section 3.2.1.2.4, IPCC, (2019b)). The low saturation state of aragonite (Ω~1) has also been observed in surface waters of the Antarctic coastal zone associated with freshwater input from glacier (Mattsdotter Björk et al., 2014) and with upwelling of deep water (Hauri et al., 2015) as well as along eastern boundary upwelling systems (Feely et al., 2016a).

Overall, in agreement with SROCC, it is *virtually certain* from these observational studies that ocean surface waters undergo acidification globally with the CO_2 increase in the atmosphere. These sustained measurements over the past decades and campaign studies of ocean carbonate chemistry also highlight with *robust evidence* that trends of acidification have been modulated by the variability and changes in physical and chemical states of ocean including those affected by the warming of the cryosphere, requiring their improved understandings.

Figure 5.20: Multi-decadal trends of pH (Total Scale) in surface layer at various sites of the oceans and a global distribution of annual mean pH adjusted to the year 2000. Time-series data of pH are from Dore et al., 2009; Olafsson et al., 2009; González-Dávila et al., 2010; Bates et al., 2014b; Takahashi et al., 2014; Wakita et al., 2017; Merlivat et al., 2018; Ono et al., 2019; and Bates and Johnson, 2020. Global distribution of annual mean pH have been evaluated from data of surface ocean pCO_2 measurements (Bakker et al., 2016; Jiang et al., 2019). Acronyms in panels: KNOT and K2 - Western Pacific subarctic gyre time-series; HOT - Hawaii Ocean Time-series; BATS - Bermuda Atlantic Time-series Study; DYFAMED - Dynamics of Atmospheric Fluxes in the Mediterranean Sea; ESTOC - European Station for Time-series in the Ocean Canary Islands; CARIACO - Carbon Retention in a Colored Ocean Time-series. Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

[END FIGURE 5.20 HERE]

5.3.3 Ocean Interior Change

5.3.3.1 Ocean Memory – Acidification in the Ocean Interior

Advances in observations and modelling for ocean physics and biogeochemistry and established knowledge of ocean carbonate chemistry show with *very high confidence* that anthropogenic CO_2 taken up into the ocean surface layer is further spreading into the ocean interior through ventilation processes including vertical mixing, diffusion, subduction and meridional overturning circulations (Sallée et al., 2012; Bopp et al., 2015; Nakano et al., 2015; Iudicone et al., 2016; Toyama et al., 2017; Perez et al., 2018; Gruber et al., 2019b) (Sections 2.3.3.5, 5.2.1.3 and 9.2.2.3) and is causing acidification in the ocean interior. The net change in oxygen consumptions by aerobic respiration of marine organisms further influences acidification by releasing CO_2 (Chen et al., 2017; Breitburg et al., 2018; Robinson, 2019) (Section 5.3.3.2).

Basin-wide and global syntheses of ocean interior carbon observations for the past decades show that the extent of acidification due to anthropogenic CO_2 invasion tends to diminish with depth (*very high confidence*) (Woosely et al., 2016;; Lauvset et al., 2020) (Carter et al., 2017a)(Figure 5.21; Section 5.2.1.3.3). The regions of deep convection such as subpolar North Atlantic and Southern Ocean present the deepest acidification detections below 2000 m (*medium confidence*). Mid-latitudinal zones within the subtropical cells and tropical regions present a relatively deep and shallow detection, respectively. A pH decrease has also been observed on the Antarctic continental shelf (Hauck et al., 2010; Williams et al., 2015). Acidification is also underway in the subsurface to intermediate layers of the Arctic Ocean due to the inflow of ventilated waters from the North Atlantic and the North Pacific (Qi et al., 2017; Ulfsbo et al., 2018).

[START FIGURE 5.21 HERE]

Figure 5.21: Spread of ocean acidification from the surface into the interior of ocean since pre-industrial times. (a) map showing the three transects used to create the cross sections shown in (b) and (c); vertical sections of the changes in (b) pH and (c) saturation state of aragonite (Ω_{arag}) between 1800–2002 due to anthropogenic CO_2 invasion (colour). Contour lines are their contemporary values in 2002. The red transect begins in the Nordic Seas and then follows the GO-SHIP lines A16 southward in the Atlantic Ocean, SR04 and S04P westward in the Southern Ocean, and P16 northward in the Pacific Ocean. The purple line follows the GO-SHIP line I09 southward in the Indian Ocean. The green line on the smaller inset crosses the Arctic Ocean from the Bering Strait to North Pole along 175°W and from the North Pole to the Fram Strait along 5°E (Lauvset et al., 2020). Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

[END FIGURE 5.21 HERE]

ACCEPTED VERSION SUBJECT TO FINAL EDITS

A significant increase in acidification resulting from net metabolic CO_2 release coupled with ocean circulation changes has been shown with *high confidence* in large swathes of intermediate waters both in the Pacific and Atlantic oceans (Byrne et al., 2010; Carter et al., 2017; Chu et al., 2016; Dore et al., 2009; Rios et a., 2015; Lauvset et al., 2020). For example, ocean circulation contributes a pH change of –0.013 ± 0.013 to the overall observed change of –0.029 ± 0.014 for 1993–2013 at depths around 1000 m at 30°S–40°S in the South Atlantic ocean (Ríos et al., 2015). Long-term repeated observations in the North Pacific show a decline in dissolved oxygen (–4.0 μmol kg^{-1} per decade at maximum) being sustained in the intermediate water since the 1980s (Takatani et al., 2012; Sasano et al., 2015), and thus the amplification of acidification associated with the weakening ventilation is thought to have been occurring persistently. In contrast, for the North Pacific subtropical mode water, large decadal variability in pH and aragonite saturation state with amplitudes of about 0.02 and about 0.1, respectively, are superimposed on secular declining trends due to anthropogenic CO_2 invasion (Oka et al., 2019). This is associated with the variability in ventilation due to the approximately 50% variation in the formation volume of the mode water that is forced remotely by the Pacific decadal oscillation (Qiu et al., 2014; Oka et al., 2015).

These trends of acidification in the ocean interior leads to *high confidence* in shoaling of the saturation horizons of calcium carbonate minerals where $\Omega = 1$. In the Pacific Ocean where the aragonite saturation horizon is shallower (a few hundred meters to 1200 m; Figure 5.21c), the rate of its shoaling is on the order of 1–2 m yr^{-1} (Feely et al., 2012; Ross et al., 2020). In contrast, shoaling rates of 4 m yr^{-1} to 1710 m for 1984–2008 and of 10–15 m yr^{-1} to 2250 m for 1991–2016 have been observed in the Iceland sea and the Irminger sea, respectively (Olafsson et al., 2009; Perez et al., 2018).

In summary, ocean acidification is spreading into the ocean interior. Its rates at depths are controlled by the ventilation of the ocean interior as well as anthropogenic CO_2 uptake at the surface, thereby diminishing with depth (*very high confidence*) (Figure 5.21). Variability in ocean circulation modulates the trend of ocean acidification at depths through the changes in ventilation and their impacts on metabolic CO_2 content, but there are large knowledge gaps of ventilation changes leading to *low confidence* in their impacts in many ocean regions (Sections 9.2.2.3 and 9.3.2; Section 5.3.3.2).

5.3.3.2 Ocean Deoxygenation and its Implications for GHGs

As summarised in SROCC (Section 5.2.2.4), there is a growing consensus that between 1970–2010 the open ocean has *very likely* lost 0.5–3.3% of its dissolved oxygen in the upper 1000 m depth (Helm et al., 2011; Ito et al., 2017; Schmidtko et al., 2017; Bindoff et al., 2019) (Section 2.3.3.6). Regionally, the equatorial and North Pacific, the Southern Ocean and the South Atlantic have shown the greatest oxygen loss of up to 30 mol m^{-2} per decade (Schmidtko et al., 2017). Warming – via solubility reduction and circulation changes –, mixing and respiration are considered the major drivers with 50% of the oxygen loss for the upper 1000 m of the global oceans attributable to the solubility reduction (Schmidtko et al., 2017). Climate variability also modifies the oxygen loss on interannual and decadal timescales especially for the tropical ocean OMZs (Deutsch et al., 2011, 2014; Llanillo et al., 2013) and the North Pacific subarctic zone (Whitney et al., 2007; Sasano et al., 2018; Cummins and Ross, 2020). However, quantifying the oxygen decline and variability and attributing them to processes in different regions remains challenging (Oschlies et al., 2018; Levin, 2018). ESMs in coupled model intercomparison project phase 5 (CMIP5) and CMIP6 corroborate the decline in ocean oxygen, and project a continuing and accelerating decline with a strong impact of natural climate variability under high emission scenarios (Bopp et al., 2013; Kwiatkowski et al., 2020; Long et al., 2016). However, CMIP5 models did not reproduce observed patterns for oxygen changes in the tropical thermocline and generally simulated only about half the oxygen loss inferred from observations (Oschlies et al., 2018). CMIP6 models have more realistic simulated mean state of ocean biogeochemistry than CMIP5 models due to improved ocean physical processes and better representation of biogeochemical processes (Séférian et al., 2020). They also exhibit enhanced ocean warming as a result of an increase in the equilibrium climate sensitivity (ECS) of CMIP6 relative to CMIP5 models, which contributes to increased stratification and reduced subsurface ventilation (4.3.1, 4.3.4, 5.3.3.2, 7.4.2, 7.5.6, 9.2.1, TS2.4). Consequently, CMIP6 model

ACCEPTED VERSION SUBJECT TO FINAL EDITS

ensembles not only reproduce the ocean deoxygenation trend of −0.30 to −1.52 mmol m^{-3} per decade between 1970–2010 reported in SROCC (Section 5.2.2.4) with a *very likely* range, but also project 32–71 % greater subsurface (100–600 m) oxygen decline relative to their RCP analogues in CMIP5, reaching to the *likely* range of decline of 6.4 ± 2.9 mmol m^{-3} under SSP1–2.6 and 13.3 ± 5.3 mmol m^{-3} under SSP5–8.5, from 1870–1899 to 2080–2099. However, they also exhibit enhanced surface ocean warming as a result of an increased climate sensitivity (ECS), which contributes to greater reduction in subsurface ventilation. Consequently, CMIP6 model ensembles now reproduce the recent observed historical ocean deoxygenation trend of −0.30 to −1.52 mmol m^{-3} per decade between 1970–2010 reported in SROCC (Section 5.2.2.4) within 90% confidence range, but project 32–71 % greater subsurface (100–600m) oxygen decline relative to their RCP analogues in CMIP5, reaching to the *likely* range of decline of 6.4 ± 2.9 mmol m^{-3} under SSP1–2.6 and 13.3 ± 5.3 mmol m^{-3} under SSP5–8.5, from 1870–1899 to 2080–2099 due to increased warming (Kwiatkowski et al., 2020). It is concluded that the oxygen content of subsurface ocean is projected to transition to historically unprecedented condition with decline over the 21st century (*medium confidence*).

In oxygen-depleted waters, microbial processes (denitrification and anammox, i.e. anaerobic ammonium oxidation) (Kuypers et al., 2005; Codispoti, 2007; Gruber and Galloway, 2008) remove fixed nitrogen, and thus when upwelled waters reach the photic zone, primary production becomes nitrogen-limited (Tyrrell and Lucas, 2002). However, in other oceanic regions, increased water-column stratification due to warming may reduce the amount of N_2O reaching the surface and thereby decrease N_2O flux to the atmosphere. Landolfi et al. (2017) suggest that by 2100, under the RCP8.5 scenario, total N_2O production in the ocean may decline by 5% and N_2O emissions be reduced by 24% relative to the pre-industrial era due to decreased organic matter export and anthropogenic driven changes in ocean circulation and atmospheric N_2O concentrations. Projected oxygen loss in the ocean is thought to result in an ocean-climate feedback through changes in the natural emission of greenhouse gases (*low confidence*).

The areas with relatively rapid oxygen decrease include OMZs in the tropical oceans, where oxygen content has been decreasing at a rate of 0.9 to 3.4 μmol kg^{-1} per decade in the thermocline for the past five decades (Stramma et al., 2008). Low oxygen, low pH and shallow aragonite saturation horizons in the OMZs of the eastern boundary upwelling regions co-occur, affecting ecosystem structure (Chavez et al., 2008) and function in the water column, including the presently unbalanced nitrogen cycle (Paulmier and Ruiz-Pino, 2009). The coupling between upwelling, productivity, and oxygen depletion feeds back to biological productivity and the role of these regions as sinks or sources of climate active gases. When OMZ waters upwell and impinge on the euphotic zone, they release significant quantities of greenhouse gases, including N_2O (0.81–1.35 TgN yr^{-1}), CH_4 (0.27–0.38 $TgCH_4$ yr^{-1}), and CO_2 (yet to be quantified) to the atmosphere, exacerbating global warming (Paulmier et al., 2008; Naqvi et al., 2010; Kock et al., 2012; Arévalo-Martínez et al., 2015; Babbin et al., 2015a; Farías et al., 2015). Modelling projections suggest a global decrease of 4 to 12% in oceanic N_2O emissions (from 3.71–4.03 TgN yr^{-1} to 3.54–3.56 TgN yr^{-1}) from 2005 to 2100 under RCP8.5, despite a tendency to increased N_2O production in the OMZs, associated primarily with denitrification (Martinez-Rey et al., 2015). It is difficult to single out the contribution of nitrification and denitrification which can occur simultaneously. A rigorous separation of these two processes would require more mechanistic parameterisations that have been hindered by the still large conceptual and parametric uncertainties (Babbin et al., 2015; Trimmer et al., 2016; Landolfi et al., 2017). Furthermore, the correlation between N_2O and oxygen varies with microorganisms present, nutrient concentrations, and other environmental variables (Voss et al., 2013).

In summary, total oceanic N_2O emissions were projected to decline by 4–12% from 2005–2100 (Martinez-Rey et al., 2015) and by 24% from the pre-industrial era to 2100 (Landolfi et al., 2017) under RCP8.5. However, there is *low confidence* in the reduction in N_2O emission to the atmosphere, because of large conceptual and parametric uncertainties, a limited number of modelling studies that explored this process, and greater oxygen losses simulated in CMIP6 models than in CMIP5 models (Kwiatkowski et al., 2020).

5.3.4 Future Projections for Ocean Acidification

5.3.4.1 Future Projections with Earth System Models

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Projections with CMIP5 ESMs, reported in AR5 (Section 6.4.4) and SROCC (Section 5.2.2.3; (IPCC, 2019b)), showed changes in global mean surface ocean pH from 1870–1899 to 2080–2099 of -0.14 ± 0.001 (inter-model standard deviation) under RCP2.6 and –0.38 ±0.005 under RCP8.5 with pronounced regional variability (Bopp et al., 2013; Hurd et al., 2018). They also projected faster pH declines in mode waters below seasonal mixed layers (Resplandy et al., 2013; Watanabe and Kawamiya, 2017) as has been observed in the Atlantic (Salt et al., 2015) and in the Pacific (Carter et al., 2019), because of the net CO_2 release by respiration and lowering CO_2 buffering capacity of seawater. In these CO_2 concentration-driven simulations, the level of acidification in the surface ocean is primarily determined by atmospheric CO_2 concentration and regional seawater carbonate chemistry, thereby providing consistent projections across models. New projections with CMIP6 ESMs show greater surface pH decline of -0.16 ± 0.002 under the SSP1–2.6 and –0.44 ± 0.005 under SSP5–8.5 from 1870–1899 to 2080–2099 (Kwiatkowski et al., 2020) (Section 4.3.2.5; Cross-Chapter Box 5.3). The greater pH declines in CMIP6 are primarily a consequence of higher atmospheric CO_2 concentrations in SSPs than their CMIP5-RCP analogues (Kwiatkowski et al., 2020). Ocean acidification is also projected to occur with *high confidence* in the abyssal bottom waters in regions such as the northern North Atlantic and the Southern Ocean (Sulpis et al., 2019), with the rates of global mean pH decline of –0.018 ±0.001 under SSP1–2.6 and –0.030 ± 0.002 under SSP5–8.5 from 1870–1899 to 2080–2099 in CMIP6 (Kwiatkowski et al., 2020).

In surface ocean, changes in the amplitude of seasonal variations in pH are also projected to occur with *high confidence.* ESMs in CMIP6 s show +73 ± 12% increase in the amplitude of seasonal variation in hydrogen ion concentration ($[H^+]$) but 10 ±5% decrease in the seasonal variation in pH (= -log $[H^+]$) from 1995–2014 to 2080–2099 under SSP5–8.5. The simultaneous amplification of $[H^+]$ and attenuation of pH seasonal cycles is counterintuitive but is the consequence of greater increase in the annual mean $[H^+]$ due to anthropogenic CO_2 invasion than the corresponding increase in its seasonal amplitude. These changes are consistent with the amplification/attenuation of the seasonal variation of +81 ±16% for $[H^+]$ and –16 ± 7% for pH from 1990–1999 to 2090–2099 under RCP8.5 in CMIP5 (Kwiatkowski and Orr, 2018).

The signal of ocean acidification in surface ocean is large and is projected to emerge beyond the range of natural variability within the time scale of a decade in all ocean basins (Schlunegger et al., 2019). There is *high agreement* among modelling studies that the largest pH decline and large-scale undersaturation of aragonite in surface seawater start to occur first in polar oceans (Orr et al., 2005; Steinacher et al., 2009; Hurd et al., 2018; Jiang et al., 2019). Under SSP5–8.5, the largest surface pH decline, exceeding 0.45 between 1995–2014 and 2080–2099, occurs in the Arctic Ocean (Kwiatkowski et al., 2020). The freshwater input from sea-ice melt is an additional factor leading to a faster decline of aragonite saturation level than expected from the anthropogenic CO_2 uptake (Yamamoto et al., 2012). The increase in riverine and glacial discharges that provide terrigenous carbon, nutrients and alkalinity as well as freshwater are the other factors modifying the rate of acidification in the Arctic Ocean. However, their impacts have been projected in a limited number of studies with extensive knowledge gaps and model simplifications leading to *low confidence* in their impacts (Terhaar et al., 2019; Hopwood et al., 2020). In the Southern Ocean, the aragonite undersaturation starts in 2030 in RCP8.5, and the area that experiences aragonite undersaturation for at least one month per year by 2100 is projected to be more than 95%. Under RCP2.6, short periods (< 1 month) of aragonite undersaturation are expected to be found in less than 2% to the area during this century (Sasse et al., 2015; Hauri et al., 2016; Negrete-García et al., 2019). These long term projections are modified at interannual timescales by large-scale climate modes (Ríos et al., 2015) such as the El Niño southern oscillation and the southern annular mode (Conrad and Lovenduski, 2015). In other regions, acidification trends are influenced by a range of processes such as changes in ocean circulation, temperature, salinity, carbon cycling, and the structure of the marine ecosystem. As, at present, models do not resolve fine-scale variability of these processes, current projections do not fully capture the changes that the marine environment will experience in the future (Takeshita et al., 2015; Turi et al., 2016).

Overall, with the rise of atmospheric CO_2, the physics of CO_2 transfer across the air-sea interface, the carbonate chemistry in seawater, the trends of ocean acidification being observed in the past decades (Section 5.3.3.2) and modelling studies described in this section, it is *virtually certain* that ocean acidification will continue to grow. However, the magnitude and sign of many of ocean carbon-climate

ACCEPTED VERSION SUBJECT TO FINAL EDITS

feedbacks are still poorly constrained (Matear and Lenton, 2014; Matear and Lenton, 2018), leading to *low confidence* in their significant and long-lasting impacts on ocean acidification.

5.3.4.2 Reversal of Ocean Acidification by Carbon Dioxide Removal

Reversing the increase in atmospheric CO_2 concentrations through negative emissions (Section 5.6) will reverse ocean acidification at the sea surface but will not result in rapid amelioration of ocean acidification in the deeper ocean (Section 5.3.3.2). The ocean's uptake of atmospheric CO_2 will start to decrease as atmospheric CO_2 decreases (Mathesius et al., 2015; Tokarska and Zickfeld, 2015) (Sections 5.4.5, 5.4.10; 5.6.2.1) However, because of the long timescales of the ocean turnover that transfers CO_2 from the upper to the deep ocean, excess carbon will continue to accumulate in the deep ocean even after a decrease in atmospheric CO_2 (Cao et al., 2014; Mathesius et al., 2015; Tokarska and Zickfeld, 2015; Li et al., 2020). There is thus *high confidence* that CO_2 emissions leave a long-term legacy in ocean acidification, and are therefore irreversible at multi-human generational scales, even with aggressive atmospheric CO_2 removal.

5.3.5 Coastal Ocean Acidification and Deoxygenation

The coastal ocean, from the shore line to the isobath of 200 m, is highly heterogeneous due to the complex interplay between physical, biogeochemical and anthropogenic factors (Gattuso et al., 1998; Chen and Borges, 2009; Dürr et al., 2011; Laruelle et al., 2014; McCormack et al., 2016). These areas, according to SROCC (Bindoff et al., 2019) are, with *high confidence*, already affected by ocean acidification and deoxygenation. This section assesses the drivers and spatial variability of acidification and deoxygenation based on new observations and data products.

5.3.5.1 Drivers

Observations and data products including models (Astor et al., 2013; Bakker et al., 2016; Kosugi et al., 2016; Vargas et al., 2016; Laruelle et al., 2017, 2018; Orselli et al., 2018; Roobaert et al., 2019; Cai et al., 2020; Sun et al., 2020a) confirm the strong spatial and temporal variability in the coastal ocean surface carbonate chemistry and sea-air CO_2 fluxes *(high agreement, robust evidence)*. The anthropogenic CO_2-induced acidification is either mitigated or enhanced through biological processes; primary production removes dissolved CO_2 from the surface, and respiration adds CO_2 and consumes oxygen in the subsurface layers. The relative intensity of these processes is controlled by natural or anthropogenic eutrophication. Other drivers of variability include biological community composition, freshwater input from rivers or ice-melting, sea-ice cover and calcium carbonate precipitation/dissolution dynamics, coastal upwelling and regional circulation, and seasonal surface cooling (Fransson et al., 2015, 2017; Feely et al., 2018; Roobaert et al., 2019; Cai et al., 2020; Hauri et al., 2020; Monteiro et al., 2020b; Sun et al., 2020a). Near-shore surface waters are often supersaturated with CO_2, regardless of the latitude, especially in highly populated areas receiving substantial amounts of domestic and industrial sewage (Chen and Borges, 2009). Nevertheless, thermal or haline stratified eutrophic coastal areas may act as net atmospheric CO_2 sinks (Chou et al., 2013; Cotovicz Jr. et al., 2015a). Continental shelves, excluding near-shore areas, act as CO_2 sinks at a rate of 0.2 ± 0.02 PgC yr^{-1} (Laruelle et al., 2014; Roobaert et al., 2019), considering ice-free areas only. Under increasing atmospheric CO_2 and eutrophication, such ecosystems would be more vulnerable to ecological and seawater chemistry changes, impacting local economy.

Since AR5, (Ciais et al., 2013) and in agreement with SROCC (IPCC, 2019b), there is now *high agreement (robust evidence)* that coastal ocean acidification, whether induced only by increasing atmospheric CO_2 or exacerbated by eutrophication or upwelling, has negative effects on specific groups of marine organisms such as reef-building corals, crabs, pteropods, and sessile fauna (Dupont et al., 2010; Bindoff et al., 2019; Bednaršek et al., 2020; Osborne et al., 2020), WGII AR6 Chapter 3), especially when combined with stressors such as temperature and deoxygenation, and potentially increased bioavailability of toxic elements such as arsenic and copper (Millero et al., 2009; Boyd et al., 2015; Breitburg et al., 2018).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Since SROCC (Bindoff et al., 2019), there is further evidence that anthropogenic eutrophication via continental runoff and atmospheric nutrient deposition, and ocean warming are *very likely* the main drivers of deoxygenation in coastal areas (Levin and Breitburg, 2015; Levin et al., 2015; Royer et al., 2016; Breitburg et al., 2018; Cocquempot et al., 2019; Fagundes et al., 2020; Limburg et al., 2020a). Increasing intensity and frequency of wind-driven upwelling is responsible for longer and more intense coastal hypoxia, fuelled by organic matter degradation from primary production *(medium to high agreement, medium evidence)* (Rabalais et al., 2010; Bakun et al., 2015; Varela et al., 2015; Fennel and Testa, 2019; Limburg et al., 2020a). Locally, submarine groundwater discharge may enhance the eutrophication state (*low agreement, limited evidence*, (Luijendijk et al., 2020)). Since AR5 (Ciais et al., 2013) and SROCC (Bindoff et al., 2019) new observations and model studies confirm the trends in increasing coastal hypoxia caused by eutrophication, ocean warming and changes in circulation (Claret et al., 2018; Dussin et al., 2019; Limburg et al., 2020a), as well as the ubiquitous impacts on marine organisms and fisheries (Carstensen and Conley, 2019; Fennel and Testa, 2019; Osma et al., 2020); WGII Chapter 3). Following open ocean deoxygenation trends, since the 1950s more than 700 coastal regions are being reported as hypoxic (dissolved oxygen concentration <2 mg O_2 L^{-1}) (Limburg et al., 2020a). Additionally, deoxygenation or increasing severe hypoxic periods in coastal areas may enhance the sea-to-air fluxes of N_2O and CH_4 especially through microbial-mediated processes in the water column-sediment interface *(medium agreement)* (Middelburg and Levin, 2009; Naqvi et al., 2010b; Farías et al., 2015; Limburg et al., 2020a).

5.3.5.2 Spatial Characteristics

There is *high agreement (robust evidence)* that heterogeneity implies different responses of coastal regions to increasing atmospheric CO_2, decreasing seawater pH and calcium carbonate saturation state, and deoxygenation (Duarte et al., 2013; Regnier et al., 2013b; Breitburg et al., 2018; Laruelle et al., 2018; Carstensen and Duarte, 2019).

There is *high agreement* that long time series of observations utilising standard methods are needed to distinguish the climate change signal in seawater carbonate chemistry from the natural variability of coastal sites (Duarte et al., 2013; Salisbury and Jönsson, 2018; IOC, 2019; Sutton et al., 2019; Tilbrook et al., 2019; Turk et al., 2019). Despite increasing availability of data and sea-air CO_2 flux budgets for the coastal ocean (Sections 5.3.5.1, 5.2.3.1), additional long-term observations are required to constrain the global time of emergence of coastal acidification. There is *high agreement* (*medium evidence*) that, for the coastal subtropical to temperate northeast Pacific and northwest Atlantic, the mean time of emergence for acidification is above two decades (Sutton et al., 2019; Turk et al., 2019).

Observations and models predict for the northeast Pacific coastal upwelling area an expansion and intensification of low-pH deep water intrusions *(high agreement, robust evidence)* (Hauri et al., 2013; Feely et al., 2016b; Cai et al., 2020). There, areas such as the California Current System are naturally exposed to intrusions of low-pH, high pCO_{2sea} deep waters from remineralisation processes and anthropogenic CO_2 intrusion (Feely et al., 2008, 2010, 2018; Chan et al., 2019; Lilly et al., 2019; Cai et al., 2020).The eastern Pacific coastal upwelling displays seasonality in subsurface aragonite undersaturation as a consequence of the interplay between anthropogenic CO_2, respiration and intrusion of upwelling waters (Feely et al., 2008, 2010, 2016, 2018; Hauri et al., 2013; Vargas et al., 2016; Chan et al., 2019; Lilly et al., 2019). The coastal southeast Pacific, upwelling combined with low-pH, low-alkalinity, organic matter-rich river inputs display extreme temporal variability in surface seawater pCO_2 and low aragonite saturation (Vargas et al., 2016; Osma et al., 2020).

Temperate, non-upwelling coastal areas along the northwest Atlantic display a trend of decreasing seawater pH, mainly attributed to the combined effects of decreasing seawater buffering capacity and eutrophication (*high agreement, robust evidence*). Observations show an increasing north to south gradient of aragonite saturation state (Sutton et al., 2016; Fennel et al., 2019; Cai et al., 2020). Low alkalinity and total inorganic carbon concentration, combined with an ocean signal of acidification, diminishes the buffering capacity along the decreasing salinity gradient from the ocean to the coast. Models suggest that in this area the

ACCEPTED VERSION SUBJECT TO FINAL EDITS

aragonite saturation is seasonally controlled by nutrient availability and primary production, supporting that eutrophication is the main driver for exacerbating acidification.(Cai et al., 2017, 2020). The coastal Gulf of Mexico is facing a parallel increase in bottom water acidification and deoxygenation off the Mississippi Delta driven by eutrophication (Cai et al., 2011; Laurent et al., 2017; Fennel et al., 2019).

Many coastal tropical are under heavy anthropogenic eutrophication induced by the effluents from large cities or receive large riverine inputs of freshwater, nutrients, and organic matter (such as Amazon, Mississippi, Orinoco, Congo, Mekong, or Changjiang rivers). Under strong eutrophication, often sub-surface and bottom waters present pH values lower than average surface open ocean (about 8.0) because increased respiration decreases pH *(high agreement, robust evidence)*, despite a net atmospheric CO_2 sink in shallow and vertically stratified coastal areas (Koné et al., 2009; Wallace et al., 2014; Cotovicz Jr. et al., 2015b; Cotovicz et al., 2018; Fennel and Testa, 2019; Lowe et al., 2019) (Section 5.3.5.1).

There is *medium evidence* from observations and models that the coastal northwestern Antarctic Peninsula (Southern Ocean) will experience calcium carbonate undersaturation by 2060, considering that anthropogenic emissions reach an atmospheric CO_2 concentration of about 500 pm at that date (Lencina-Avila et al., 2018; Monteiro et al., 2020a). The synergies among warming, meltwater, sea-air CO_2 equilibrium and circulation may, to some extent, offset the coastal ocean acidification trends in Antarctica (Henley et al., 2020). In the coastal western Arctic Ocean, there is increasing *robust evidence* that ocean acidification is driven by sea-air CO_2 fluxes and sea-ice melt and increasing intrusions since the 1990s of low-alkalinity Pacific water, lowering aragonite saturation state (Qi et al., 2017, 2020; Cross et al., 2018). The Bering Sea (northeastern Pacific) shows decreasing trends in calcium carbonate saturation, associated to the increasing atmospheric CO_2 uptake combined with riverine freshwater and carbon inputs *(high agreement, robust evidence)* (Pilcher et al., 2019; Sun et al., 2020a).

The spatial distribution of hypoxic areas is highly heterogeneous in the coastal ocean, and there is *high agreement, robust evidence* that more severe hypoxia or anoxia is often associated to highly populated coastal areas, or local circulation and upwelling, and seasonal stratification lead to an accumulation of organic matter in subsurface waters (Ciais et al., 2013; Rabalais et al., 2014; Li et al., 2016b; Breitburg et al., 2018; Bindoff et al., 2019) (SROCC Chapter 5; IPCC, (2019b)). The causes and trends of coastal deoxygenation can only be assessed by making available long-term time series combined to regional modelling (Fennel and Testa, 2019), as in the California current system (Wang et al., 2017), the East China Sea (Chen et al., 2007; Qian et al., 2017), the Namibian or along the northwestern Atlantic shelves (Claret et al., 2018). Other coastal upwelling sites such as the Arabian Sea display seasonal hypoxia but no worsening trends (Gupta et al., 2016).

The Baltic Sea is the largest semi-enclosed sea where hypoxia is reported to have happened before the 1950s (Carstensen et al., 2014; Rabalais et al., 2014; Łukawska-Matuszewska et al., 2019). The frequency and volume of seawater inflow from the North Sea decreased after 1950, leading to an expansion of hypoxic areas from 40,000 to 60,000 km² in combination with increasing eutrophication (Carstensen et al., 2014). From the available observations, there is *robust evidence* that many areas in the Baltic Sea are experiencing deoxygenation despite efforts to reduce nutrient loads (Lennartz et al., 2014; Jokinen et al., 2018).

There is *medium agreement (medium evidence)* that just by reducing anthropogenic nutrient inputs may lead to less severe coastal hypoxic conditions, as observed in the coastal north-western Adriatic Sea (Djakovac et al. (2015). However, low-oxygen sediments may remain a long-term source of phosphorus and ammonium to the water column, fuelling primary production (Jokinen et al., 2018; Fennel and Testa, 2019; Limburg et al., 2020b).

5.4 Biogeochemical Feedbacks on Climate Change

This section covers biogeochemical feedbacks on climate change, which represent one of the largest sources of uncertainty in climate change projections. The relevant processes are discussed (Sections 5.4.1 to 5.4.4), prior to discussing the simulation and projection of the carbon cycle in Earth system models (Section 5.4.5),

ACCEPTED VERSION SUBJECT TO FINAL EDITS

emergent constraints on future projections (Section 5.4.7), non-CO_2 feedbacks (Section 5.4.7), and possible biogeochemical abrupt changes (Section 5.4.8).

5.4.1 Direct CO_2 Effect on Land Carbon Uptake

AR5 (WGI, Box 6.3) and SRCCL (IPCC, 2019a) concluded with *high confidence* that rising atmospheric CO_2 increases leaf-level photosynthesis. This effect is represented in all ESMs. New studies since AR5 add evidence that the leaf-level CO_2 fertilisation is modulated by acclimation of photosynthesis to long-term CO_2 exposure, growth temperature, seasonal drought, and nutrient availability, but these effects are not yet routinely represented in ESMs (Smith and Dukes, 2013; Baig et al., 2015; Kelly et al., 2016; Drake et al., 2017; Jiang et al., 2020a). Cross-Chapter Box 5.1 assesses multiple lines of evidence, which suggest that the ratio of plant CO_2 uptake to water loss (plant water-use efficiency; WUE) increases in near proportionality to atmospheric CO_2. Despite advances in the regional coverage of field experiments, observations of the consequences of CO_2 fertilisation at ecosystem level are still scarce, in particular from outside the temperate zone (Song et al., 2019a). New syntheses since AR5 corroborate that the effect of elevated CO_2 on plant growth and ecosystem carbon storage is generally positive (*high confidence*), but is modulated by temperature, water and nutrient availability (Reich et al., 2014; Obermeier et al., 2017; Peñuelas et al., 2017; Hovenden et al., 2019; Song et al., 2019a). Plant carbon allocation, changes in plant community composition, disturbance, and natural plant mortality are important processes affecting the magnitude of the response, but are currently poorly represented in models (De Kauwe et al., 2014; Friend et al., 2014; Reich et al., 2018; Walker et al., 2019a; Yu et al., 2019), and thus contribute strongly to uncertainty in ESM projections (Arora et al., 2020).

Field studies with elevated CO_2 have demonstrated that the initial stimulation of above-ground growth may decline if insufficient nutrients such as nitrogen or phosphorus are available (Finzi et al., 2007; Norby et al., 2010; Hungate et al., 2013; Reich and Hobbie, 2013; Talhelm et al., 2014; Terrer et al., 2018). Model-data syntheses have demonstrated that the ability to capture the observed long-term effect of elevated CO_2 depends on the ability of models to predict the effect of vegetation on soil biogeochemistry (Zaehle et al., 2014; Koven et al., 2015; Medlyn et al., 2015; Walker et al., 2015). Meta-analyses of CO_2 manipulation experiments point to increased soil microbial activity and accelerated turnover of soil organic matter (van Groenigen et al., 2017) as a result of increased below-ground carbon allocation by plants (Song et al., 2019b), and increased root exudation or mycorrhizal activity due to enhanced plant nutrient requirements under elevated CO_2 (Drake et al., 2011; Terrer et al., 2016; Meier et al., 2017). These effects are not considered in most ESMs. One global model that attempts to represent these processes suggests that elevated CO_2 related carbon accumulation is reduced in soils but increased in vegetation relative to more conventional models (Sulman et al., 2019).

Our understanding of the effects of phosphorus limitation is less developed than for nitrogen, but a growing body of literature suggests it is as important, particularly in regions with highly weathered soils (Wang et al., 2018; Terrer et al., 2019; Du et al., 2020). CO_2 experiments collectively show that soil phosphorus is an important constraint on the CO_2 fertilisation effect on plant biomass (Terrer et al., 2019; Jiang et al., 2020a). Indeed, a free-air CO_2 enrichment experiment in a phosphorus-limited mature forest ecosystem did not find an increase in biomass production despite increases in photosynthesis after four years of CO_2 exposure (Jiang et al., 2020b). The lack of free-air CO_2 enrichment experiments in phosphorus-limited tropical forests limits our understanding on the role of phosphorus availability in constraining the CO_2 fertilisation effect globally (Norby et al., 2016; Fleischer et al., 2019). Models accounting for the effects of phosphorus availability, in addition to nitrogen, generally show an even stronger reduction of the response of ecosystem carbon storage to elevated CO_2 (Goll et al., 2012; Zhang et al., 2014; Yang et al., 2019b). Insufficient data and uncertainties in the process formulation cause large uncertainty in the magnitude of this effect (Medlyn et al., 2016; Fleischer et al., 2019).

Consistent with AR5 (WGI, Section 6.4.2), the CO_2 fertilisation effect is the dominant cause for the projected increase in land carbon uptake between 1860 and 2100 in ESMs (Figures 5.26, 5.27; Table 5.5; Arora et al., 2020). In the CMIP6 ensemble, the increase of land carbon storage due to CO_2 fertilisation is a global

ACCEPTED VERSION SUBJECT TO FINAL EDITS

phenomenon but is strongest in the tropics (Figure 5.26). The resulting increase of productivity is a key driver of increases in vegetation and soil carbon storage. However, consistent with earlier findings (Todd-Brown et al., 2013; Friend et al., 2014; Hajima et al., 2014), processes affecting vegetation carbon-use efficiency and turnover such as allocation changes, mortality, and vegetation structural changes, as well as the pre-industrial soil carbon turnover time, also play an important role (Arora et al., 2020).

As a major advance since AR5 (WGI, Section 6.4.2), 6 out of 11 models in the C^4MIP-CMIP6 ensemble account for nitrogen cycle dynamics over land (Table 5.4). On average, these models exhibit a 25–30% lower CO_2 fertilisation effect on land carbon storage, compared to models that do not (Figures 5.29, Table 5.5). The only model in the C^4MIP-CMIP6 ensemble that explicitly represents the effect of P availability on plant growth suggests the lowest C storage response to increasing CO_2 (Arora et al., 2020). The lower CO_2 effect due to decreased nutrient availability is generally consistent with analyses of the implicit nutrient limitation in CMIP5 simulations (Wieder et al., 2015; Zaehle et al., 2015) and independent assessments by stand-alone land models (Zaehle et al., 2010; Wårlind et al., 2014; Zhang et al., 2014; Goll et al., 2017; Meyerholt et al., 2020a). The simulated effects are generally consistent with expectations based on independent observations (Walker et al., 2020). However, the magnitude of nutrient feedbacks in these models is poorly constrained by observations, owing to the limited geographic distribution of available observations and the uncertain scaling of results obtained from manipulation experiments to transient system dynamics (Song et al., 2019a; Wieder et al., 2019; Meyerholt et al., 2020a).

Our understanding of the various biological processes, which affect the strength of the CO_2 fertilisation effect on photosynthesis and its impact on carbon storage in vegetation and soils, in particular regarding the limitations imposed by nitrogen and phosphorus availability, has developed since AR5 (WGI, Box 6.2). Based on consistent behaviour across all CMIP6 ESMs, there is *high confidence* that CO_2 fertilisation of photosynthesis acts as an important negative feedback on anthropogenic climate change, by reducing the rate at which CO_2 accumulates in the atmosphere. Since AR5 (WGI, Box 6.2), an increasing number of CMIP6 ESMs account for nutrient cycles and the consistent results found in their model projections suggests with *high confidence* that limited nutrient availability will limit the CO_2 fertilisation effect (Arora et al., 2020). The magnitude of both the direct CO_2 effect on land carbon uptake, and its limitation by nutrients, remains uncertain (*low confidence*).

5.4.2 Direct CO_2 Effects on Projected Ocean Carbon Uptake

In AR5 (WGI, Section 6.4.2) there was *high agreement* that CMIP5 ESMs project continued ocean CO_2 uptake through to 2100, with higher uptake corresponding to higher concentration or emission pathways. There has been no significant change in the magnitude of the sensitivity of ocean carbon uptake to increasing atmospheric CO_2, or in the inter-model spread, between the CMIP5 and CMIP6 era (Arora et al., 2020). The analysis from both emissions and concentration driven CMIP5 models projections show that the ocean sink stops growing beyond 2050 across all emission scenarios (Section 5.4.5.3). CMIP6 models also show a similar time-evolution of global ocean CO_2 uptake to CMIP5 models over the 21st century (Figure 5.25) with decreasing net ocean CO_2 uptake ratio to anthropogenic CO_2 emissions under SSP5–8.5.

The projected weakening of ocean carbon uptake is driven by a combination of decreasing carbonate buffering capacity and warming which are positive feedbacks under weak to no mitigation scenarios (SSP4 and 5). In high mitigation scenarios (SSP1–2.6), weakening ocean carbon uptake is driven by decreasing emissions (Cross-Chapter Box 5.3). The detailed understanding of carbonate chemistry in seawater that has accumulated over more than half a century (e.g. Egleston et al., 2010; Revelle & Suess, 1957), provides *high confidence* that the excess CO_2 dissolved in seawater leads to a nonlinear reduction of the CO_2 buffering capacity, that is smaller dissolved inorganic carbon (DIC) increase with respect to pCO_2 increase along with the increase in cumulative ocean CO_2 uptake. Recent studies (Katavouta et al., 2018; Jiang et al., 2019; Arora et al., 2020; Rodgers et al., 2020) suggest with *medium confidence* that the decrease in the ocean CO_2 uptake ratio to anthropogenic CO_2 emission under low to no mitigation scenarios over the 21st century is predominantly attributable to the ocean carbon-concentration feedback through the reduction of the seawater CO_2 buffering capacity but with contributions from physical drivers such as warming and wind stress

ACCEPTED VERSION SUBJECT TO FINAL EDITS

(*medium confidence*) and biological drivers (*low confidence*) (Sections 5.2.1.3.3, 5.4.4).

Projected increases in ocean DIC due to anthropogenic CO_2 uptake amplify the sensitivity of carbonate system variables to perturbations of DIC in the surface ocean, for example via the amplitude of the seasonal cycle of pCO_2, which impact the mean annual air-sea fluxes (Fassbender et al., 2018; Hauck et al., 2015; Landschützer et al., 2018; SROCC Section 5.2.2.3). A larger amplification of the surface ocean pCO_2 seasonality occurs in the subtropics where pCO_2 seasonality is dominated by temperature seasonality, with the summer increase in the difference in pCO_2 between surface water and the overlying atmosphere reaching 3µatm per decade between 1990 and 2030 under RCP8.5 (Schlunegger et al., 2019; Rodgers et al., 2020). In contrast, the impact of biological production on the seasonal cycle of pCO_2 in summer in the Southern Ocean strengthens the drawdown of CO_2 (Hauck et al., 2015).

Overall, there is *medium confidence* on three outcomes in the ocean from projected CO_2 uptake under medium to high CO_2 concentration scenarios: (i) a strengthening positive feedback, which impacts on the airborne fraction via the reduction of the ocean CO_2 buffering capacity due to cumulative ocean CO_2 uptake, which reduces the net ocean CO_2 uptake ratio to anthropogenic CO_2 emission (Katavouta et al., 2018; Arora et al., 2020; Rodgers et al., 2020); (ii) an amplification of the seasonal cycle of CO_2 variables, which impact both the ocean sink and ocean acidification (Hauck et al., 2015); (iii) a decrease in the aragonite and calcite saturation levels in the ocean which negatively impacts the calcification rates of marine organisms (*high confidence*) and which forms a negative feedback on the uptake of CO_2 (McNeil and Sasse, 2016) (Cross-Chapter Box 5.3).

5.4.3 Climate Effect on Land Carbon Uptake

AR5 assessed with *medium confidence*, that future climate change will decrease land carbon uptake relative to the case with constant climate, but with a poorly-constrained magnitude (WGI, Chapter 6, Executive Summary). Ongoing uncertainty in the magnitude and geographic pattern of the feedbacks (Section 5.4.5), continues to support a *medium confidence* assessment that future climate change will decrease land carbon uptake relative to the case with constant climate.

5.4.3.1 Plant Physiology

Plant productivity is highly dependent on local climate. In cold environments, warming has generally led to an earlier onset of the growing season, and with it an increase in early-season vegetation productivity (e.g. Forkel et al., 2016). However, this trend is affected by adverse effects of climate variability, and other emerging limitations on vegetation production by water, energy and nutrients, which may gradually reduce the effects of warming (Piao et al., 2017; Buermann et al., 2018; Liu et al., 2019). At centennial timescales, boreal forest expansion may act as a climate-driven carbon sink (Pugh et al., 2018).

In tropical and temperate environments, temperature simultaneously affects the metabolic rates of photosynthetic processes within leaf tissues as well as the vapor pressure deficit that drives transpiration, its control by leaf stomata, and the resulting soil and plant tissue water content. Thus the direct effect of warming on photosynthesis can be positive, negative, or invariant depending on environmental context (Lin et al., 2012; Yamori et al., 2014; Smith and Dukes, 2017; Grossiord et al., 2020). Observations and models suggest that the vapour pressure deficit effects are stronger than direct temperature effects on enzyme activities (Smith et al., 2020), and that acclimation of photosynthetic optimal temperature may mitigate productivity losses of tropical forests under climate change (Kattge and Knorr, 2007; Tan et al., 2017; Kumarathunge et al., 2019). Some models have begun to include these acclimation responses, both in photosynthesis and autotrophic respiration (Lombardozzi et al., 2015; Smith et al., 2015; Huntingford et al., 2017; Mercado et al., 2018).

5.4.3.2 Fire and Other Disturbances

ACCEPTED VERSION SUBJECT TO FINAL EDITS

SRCCL assessed that climate change is playing an increasing role in determining wildfire regimes alongside human activity (*medium confidence*), with future climate variability expected to enhance the recurrence and severity of wildfires in many biomes, such as tropical rainforests (*high confidence*). Projections of increased fire weather in a warmer climate are widespread (Section 12.3.2.8) and may drive increased fire frequency and severity in several regions, including Arctic and boreal ecosystems (Gauthier et al., 2015; Walker et al., 2019b), Mediterranean-type ecosystems (Turco et al., 2014; Jin et al., 2015), degraded tropical forests (Aragão et al., 2018), and tropical forest-savanna transition zones (Lehmann et al., 2014).

Wildfire is included in some CMIP6 ESMs (Table 5.4) and is thus only partially represented in estimates of carbon-climate feedbacks from these models. The CMIP5 ESMs that include fire project 8–58% increases of fire carbon emissions under future scenarios, with higher emissions under higher-warming scenarios; the ensemble spread is driven by differing factors such as population density, fire management, and other land-use processes (Kloster and Lasslop, 2017). Fire dynamics in CMIP6 models, as evaluated in land-only configurations of CMIP6-generation land surface models, also show large variations but better agreement with observations (Teckentrup et al., 2019; Hantson et al., 2020; Lasslop et al., 2020).

Climate change also drives changes to vegetation composition and ecosystem carbon storage through other disturbances such as forest dieback that lead to biome shifts in tropical forests (Cox et al., 2004; Jones et al., 2009; Brando et al., 2014; Le Page et al., 2017; Zemp et al., 2017), and temperate and boreal regions (Joos et al., 2001; Lucht et al., 2006; Scheffer et al., 2012; Lasslop et al., 2016). AR5 assessed that large-scale loss of tropical forests due to climate change is *unlikely* (WGI, Section 6.4.9). Newer ecosystem modelling approaches that include a greater degree of ecosystem heterogeneity and diversity show a reduced sensitivity of such forest dieback-type changes (Levine et al., 2016; Sakschewski et al., 2016), supporting the AR5 assessment (Section 5.4.8). Beyond such biome shifts, observations of tropical forests also show that increasing tree mortality rates within tropical forests may reduce carbon turnover times and storage (Brienen et al., 2015), that increased tree mortality rates in tropical forests and elsewhere are expected with increased temperatures and vapor pressure deficit (Cross-chapter Box 5.1; (Allen et al., 2015; McDowell et al., 2018; Grossiord et al., 2020), and that these processes are not well represented in ESMs (Powell et al., 2013; Fisher et al., 2018). An ensemble of land models that include ecological processes such as forest demography shows that changes to mortality may be a more important driver of carbon dynamics than changes to productivity (Friend et al., 2014).

Overall, climate change will force widespread increases in fire weather throughout the world (Section 12.3.2.8). Because of incomplete inclusion of fire in ESMs, a separate compilation of fire-driven carbon-climate feedback estimates (Eliseev et al., 2014a; Harrison et al., 2018) (section 5.4.8). There is *low agreement* in magnitude and *medium agreement* in sign, which alongside other literature (Jones et al., 2020), leads to an assessment of *medium confidence* that fire represents a positive carbon-climate feedback, but *very low confidence* in the magnitude of that feedback. Other disturbances such as tree mortality will increase across several ecosystems (*medium agreement*) with decreased vegetation carbon (*medium confidence*). However, the lack of model agreement and lack of key process representation in ESMs lead to a *low confidence* assessment in the projected magnitude of this feedback.

5.4.3.3 Soil Carbon

Changes to soil carbon stocks in response to climate change are a potentially strong positive feedback (Cox et al., 2000). Since the AR5 (WGI, Section 6.4.2), there has been progress made in understanding soil carbon dynamics, and associated feedbacks. These include: (i) an increased understanding of and ability to quantify high latitude soil carbon feedbacks (Box 5.1); (ii) increased understanding of the causes responsible for soil carbon persistence on long timescales, particularly the interactions between decomposers and soil organic matter and mineral assemblages (Kleber et al., 2007; Schmidt et al., 2011; Luo et al., 2016); and (iii) increased understanding of soil carbon dynamics in subsurface layers (Hicks Pries et al., 2017; Balesdent et al., 2018).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

CMIP6 ESMs predict losses of soil carbon with warming, which are larger than climate-driven vegetation carbon losses (Arora et al., 2020). As in CMIP5 (Todd-Brown et al., 2013), there is also a large CMIP6 ensemble spread in climate-driven soil carbon changes, partially driven by a large spread in the current soil carbon stocks predicted by the models. In CMIP5 ESMs, much of the soil carbon losses with warming can be traced to decreased carbon inputs, with a weaker contribution from changing soil carbon lifetimes due to faster decomposition rates (Koven et al., 2015a), which may be an artefact of the lack of permafrost carbon (Box 5.1). Isotopic constraints suggest that CMIP5 ESMs systematically overestimated the transient sensitivity of soil ^{14}C responses to atmospheric ^{14}C changes, implying that the models respond too quickly to changes in either inputs or turnover times and that the soil contribution to all feedbacks may thus be weaker than currently projected (He et al., 2016). Using natural gradients of soil carbon turnover as a constraint on long-term responses to warming suggests that both CMIP5 and CMIP6 ESMs may systematically underestimate the temperature sensitivity at high latitudes, and may overestimate the temperature sensitivity in the tropics (Koven et al., 2017; Wieder et al., 2018; Varney et al., 2020), although experimental soil warming in tropical forests suggest high sensitivity of decomposition to warming in those regions as well (Nottingham et al., 2020).

Peat soils, where thick organic layers build up due to saturated and anoxic conditions, represent another possible source of carbon to the atmosphere. Peats could dry, and decompose or burn as a result of climate change in both high (Chaudhary et al., 2020) and tropical (Cobb et al., 2017) latitudes, and in combination with anthropogenic drainage of peatlands (Warren et al., 2017). Peat carbon dynamics are not included in the majority of CMIP6 ESMs.

Soil microbial dynamics shift in response to temperature, giving rise to complex longer-term trophic effects that are more complex than the short-term sensitivity of decomposition to temperature. Such responses are observed in response to long-term warming experiments (Melillo et al., 2017). While most CMIP6 ESMs do not include microbial dynamics, simplified global soil models that do include such dynamics show greater uncertainty in projections of soil C changes, despite agreeing more closely with current observations, than the linear models used in most ESMs (Wieder et al., 2013; Guenet et al., 2018).

In nutrient limited ecosystems, prolonged soil warming can induce a fertilisation effect through increased decomposition, which increases nutrient availability and thereby vegetation productivity (Melillo et al., 2011). Models that include this process tend to show a weaker carbon-climate feedback than those that do not (Thornton et al., 2009; Zaehle et al., 2010; Wårlind et al., 2014; Meyerholt et al., 2020b). In CMIP6, 6 out of 11 ESMs include a representation of the nitrogen cycle, and the mean of those models predicts a weaker carbon-climate feedback than the overall ensemble mean (Arora et al., 2020) (Section 5.4.8). These models only partly account for the interactions of nutrient effects with other processes such as shifts of vegetation zones under climate changes (Sakaguchi et al., 2016) leading to either changes in species composition or changes in plant tissue nutrient to carbon ratios (Thomas et al., 2015; Achat et al., 2016; Du et al., 2019).

The *high agreement* and multiple lines of evidence that warming increases decomposition rates lead to *high confidence* that warming will overall result in carbon losses relative to a constant climate and contribute to the positive carbon-climate feedback (Section 5.4.8). However, the widespread in ESM projections and lack of model representation of key processes that may amplify or mitigate soil carbon losses on longer timescales (including microbial dynamics, permafrost, peatlands, and nutrients) lead to *low confidence* in the magnitude of global soil carbon losses with warming.

[START BOX 5.1 HERE]

BOX 5.1: Permafrost Carbon and Feedbacks to Climate

What is permafrost carbon and why should we be concerned about it?

Soils in the Arctic and other cold regions contain perennially frozen layers, known as permafrost. Soils in the

ACCEPTED VERSION SUBJECT TO FINAL EDITS

northern permafrost region store a large amount of organic carbon, estimated at 1460–1600 PgC across both surface soils and deeper deposits (Hugelius et al., 2014; Strauss et al., 2017; Mishra et al., 2021). Of that carbon, permafrost soils and deposits store 1070–1360 PgC, of which 300–400 PgC are in the first meter, and the rest at depth. The remaining 280–340 Pg C are in permafrost-free soils within the permafrost region. These carbon deposits have accumulated over thousands of years due to the slow rates of organic matter decomposition in frozen and/or waterlogged soil layers, but these frozen soils are highly decomposable upon thaw (Schädel et al., 2014).

Is permafrost carbon already thawing and emitting greenhouse gases?

The permafrost region was a historic carbon sink over centuries to millennia (*high confidence*) (Loisel et al., 2014; Lindgren et al., 2018). Currently though, thawing soils due to anthropogenic warming are losing carbon from the decomposition of old frozen organic matter, as found via ^{14}C signature of respiration at sites undergoing rapid permafrost thaw (Hicks Pries et al., 2013), of dissolved organic carbon in rivers draining watersheds with permafrost thaw (Vonk et al., 2015; Wild et al., 2019), and of CH_4 produced in thawing lakes (Walter Anthony et al., 2016).

Despite accumulating evidence of increased carbon losses, it is difficult to scale up site- and ecosystem-level measurements to assess the net carbon balance over the entire permafrost region, due to the high spatial heterogeneity, the strong seasonal cycles and the difficulty in monitoring these regions consistently across the year. SROCC assessed with *high confidence* both that ecosystems in the permafrost region act as carbon sinks during the summer growing season, and that wintertime carbon losses are significant, consistent with a multi-decadal small increase in CO_2 emissions during early winter at Barrow, Alaska (Sweeney et al., 2016; Webb et al., 2016; Meredith et al., 2019). These findings have been further strengthened by recent comprehensive synthesis of in-situ wintertime flux observations that show large carbon losses during the non-growing season (Natali et al., 2019). Increased autumn and winter respiration are a key large-scale fingerprint of top-down permafrost thaw predicted by ecosystem models (Parazoo et al., 2018). However, the length of these wintertime observational records is too short to unequivocally determine whether winter carbon losses are higher now than they used to be. One study inferred a multi-year net CO_2 source for the tundra in Alaska (Commane et al., 2017), which is equivalent to 0.3 PgC yr^{-1} when scaled up to the northern permafrost region (*low confidence*) (Meredith et al., 2019).

Since the AR5, evidence of a more active carbon cycle in the northern high latitude regions has also been observed through the increased amplitude of CO_2 seasonal cycles. However, the relative roles of local sources versus influence from mid-latitudes makes it difficult to infer changes to Arctic ecosystems from these observations (Graven et al., 2013; Forkel et al., 2016; Takata et al., 2017; Bruhwiler et al., 2021). Estimates of CO_2 fluxes with atmospheric inversion models showed an enhanced seasonal cycle amplitude but no significant trends in annual total fluxes, in agreement with flux tower measurements over one decade (2004–2013) (Welp et al., 2016; Takata et al., 2017).

In addition to CO_2, CH_4 emissions from the northern permafrost region contribute to the global methane budget, but evidence as to whether these emissions have increased from thawing permafrost is mixed. SROCC assigned *low confidence* to the degree of recent additional methane emissions from diverse sources throughout the permafrost region. These include observed regional lake area change, which suggest a 1.6–5 Tg CH_4 yr^{-1} increase over the last 50 years (Walter Anthony et al., 2016), ice-capped geological sources (Walter Anthony et al., 2012; Kohnert et al., 2017), and shallow Arctic Ocean shelves. The shallow subsea emissions are particularly uncertain due to both the wide range of estimates (3 Tg CH_4 yr^{-1}(Thornton et al., 2016a) to 17 Tg CH_4 yr^{-1} (Shakhova et al., 2014)), and the lack of a baseline with which to infer any changes; the upper half of this range in flux estimates is, however, inconsistent with the atmospheric inversions constrained by the pan-Arctic CH_4 concentration measurements (Berchet et al., 2016).

Atmospheric measurements and inversions performed at the global and regional scales do not show any detectable trends in annual mean CH_4 emissions from the permafrost region over the past 30 years (Jackson et al., 2020; Saunois et al., 2020; Bruhwiler et al., 2021), consistent with atmospheric measurements in Alaska that showed no significant annual trends despite significant increase in air temperature (Sweeney et

ACCEPTED VERSION SUBJECT TO FINAL EDITS

al., 2016). Atmospheric inversions and biospheric models do not show any clear trends in CH_4 emission for wetland regions of the high latitudes during the period 2000–2016 (Patra et al., 2016; Poulter et al., 2017; Jackson et al., 2020; Saunois et al., 2020). Large uncertainties on wetland extent and limited data constraints place *low confidence* in these modeling approaches.

SROCC also assessed with *high confidence* that methane fluxes have been under-observed due to their high variability at multiple scales in both space and time, and that there is a persistent mismatch between top-down and bottom-up methane budgets, with emissions calculated by upscaling ground observations typically higher than emissions inferred from large-scale atmospheric observations (Thornton et al., 2016b).

In conclusion, there is *high confidence* that the permafrost region has acted as a historic carbon sink over centuries to millennia and *high confidence* that some permafrost regions are currently net sources of CO_2. There is *robust evidence* that some CH_4 emissions sources and for some regions have increased over the past decades (*medium confidence*). For the northern permafrost-wide region, no multi-decadal trend has been detected on CO_2 and CH_4 fluxes but given the low resolution and sparse observations of current observations and modeling sytems, we place *low confidence* in this statement.

Since AR5, there have been new studies showing that permafrost thaw also leads to N_2O release from soil (Abbott and Jones, 2015; Karelin et al., 2017; Wilkerson et al., 2019), a previously unaccounted source. However, this release is unquantified at the pan-Arctic scale.

What does the paleo record tell us about how much emissions to expect?

Large areas of Alaska and Siberia are underlain by frozen, glacial-age, ice- and carbon-rich deposits, and many of these areas show evidence of thermokarst processes during Holocene warm periods. Rapid warming of high northern latitudes contributed to permafrost thaw, liberating labile organic carbon to the atmosphere (Köhler et al., 2014; Crichton et al., 2016; Winterfeld et al., 2018; Meyer et al., 2019), supporting the vulnerability of these areas to further warming (Strauss et al., 2013, 2017).

Radiogenic and stable isotopic measurements on CH_4 trapped in Antarctic ice support the view that CH_4 emissions from fossil carbon reservoirs, including permafrost and methane hydrates, in response to the deglacial warming remained small. Mass-balance calculations reveal that geological CH_4 emissions have not exceeded 19 Tg yr^{-1}, highlighting that the deglacial increase in CH_4 emissions were predominantly related to contemporary methane emissions from tropical wetlands and seasonally inundated floodplains (Bock et al., 2017; Petrenko et al., 2017; Dyonisius et al., 2020). Isotopic constraints on CO_2 losses from permafrost with warming after the Last Glacial Maximumm (LGM) are weaker than for CH_4. While the biosphere as a whole held less carbon during LGM than the preindustrial, that change in stocks was smaller than the change in plant productivity, and so carbon losses at high latitudes may have been offset by increased tropical productivity in response to warming during the last deglacial transition (LDT) (Ciais et al., 2012b). There is also paleoclimate evidence for processes that mitigate carbon losses with warming on longer timescales, such as longer-term carbon accumulation in lake deposits following thermokarst thaw (Walter Anthony et al., 2014), and long-term accumulation of carbon in permafrost soils following LDT carbon loss (Lindgren et al., 2018), particularly in peatlands which accumulated carbon at a slow but persistent rate in warm paleoclimates (Treat et al., 2019).

In conclusion, several independent lines of evidence indicate that permafrost thaw did not release vast quantities of fossil CH_4 associated with the transient warming events of the LDT, suggesting that large emissions of CH_4 from old carbon sources will not to occur in response to future warming (*medium confidence*).

How much emissions do we expect in the future?

Near-surface permafrost is projected to decrease significantly under future global warming scenarios (*high confidence,* Section 9.5.2), thus creating the potential for releasing CO_2 and CH_4 to the atmosphere, and act as a positive carbon-climate feedback.

ACCEPTED VERSION SUBJECT TO FINAL EDITS

The processes that govern permafrost carbon loss are grouped into gradual and abrupt mechanisms. Gradual processes include the deepening of the seasonally-thawed active layer into perennially-frozen permafrost layers and lengthening of the thawed season within the active layer, which increases the amount of organic carbon that is thawed and the duration of thaw. Abrupt thaw processes include ice-wedge polygon degradation, hillslope collapse, thermokarst lake expansion and draining, all of which are processes largely occurring in regions with very high soil carbon content (Olefeldt et al., 2016a, 2016b). Abrupt thaw processes can contribute up to half of the total net greenhouse gas release from permafrost loss, the rest attributed to gradual thaw (Schneider von Deimling et al., 2015; Turetsky et al., 2020). Increased fire frequency and severity (Hu et al., 2010) also contributes to abrupt emissions and the removal of the insulating cover which leads to an acceleration of permafrost thaw (Genet et al., 2013). Ecological feedbacks can both mitigate and amplify carbon losses: nutrient release from increased organic matter decomposition can drive vegetation growth that partially offsets soil carbon losses (Salmon et al., 2016), but also lead to biophysical feedbacks that further amplify warming (Myers-Smith et al., 2011).

Through CMIP5, Earth system models (ESMs) had not included permafrost carbon dynamics. This remains largely true in CMIP6, with most models not representing permafrost carbon processes, a small number representing the active-layer thickening effect on decomposition (Table 5.4), and no ESMs representing thermokarst or fire-permafrost-carbon interactions. The CMIP6 ensemble mean predicts a negative carbon-climate feedback in the permafrost region. However, those that do include permafrost carbon show a positive carbon-climate feedback in the permafrost region (Figure 5.27). Given the current limited ESM capacity to assess permafrost feedbacks, estimates in this report are based on published permafrost-enabled land surface model results.

SROCC assessed that warming under a high emission scenario (RCP8.5 or similar) would result in a loss of permafrost carbon by 2100 of 10s to 100s of PgC, with a maximum estimate of 240 PgC and a best estimate of 92 ± 17 PgC (Meredith et al., 2019) (SROCC, Figure 3.11). Under lower emissions scenarios, Schneider von Deimling et al., (2015) estimated permafrost feedbacks of 20–58 PgC of CO_2 by 2100 under a RCP2.6 scenario, and 28–92 PgC of CO_2 under a RCP4.5 scenario.

This new assessment, based on studies included in or published since SROCC (Schaefer et al., 2014; Koven et al., 2015c; Schneider von Deimling et al., 2015; Schuur et al., 2015; MacDougall and Knutti, 2016a; Gasser et al., 2018; Yokohata et al., 2020), estimates that the permafrost CO_2 feedback per degree of global warming (Figure 5.29) is 18 (3.1–41, 5th–95th percentile range) PgC $^{o}C^{-1}$. The assessment is based on a wide range of scenarios evaluated at 2100, and an assessed estimate of the permafrost CH_4-climate feedback at 2.8 (0.7–7.3 5th–95th percentile range) Pg Ceq $^{o}C^{-1}$ (Figure 5.29). This feedback affects the remaining carbon budgets for climate stabilisation and is included in their assessment (Section 5.5.2).

Beyond 2100, models suggest that the magnitude of the permafrost carbon feedback strengthens considerably over the period 2100–2300 under a high-emissions scenario (Schneider von Deimling et al., 2015; McGuire et al., 2018). Schneider von Deimling et al., (2015) estimated that thawing permafrost could release 20–40 PgC of CO_2 in the period from 2100 to 2300 under a RCP2.6 scenario, and 115–172 PgC of CO_2 under a RCP8.5 scenario. The multi-model ensemble in (McGuire et al., 2018) project a much wider range of permafrost soil carbon losses of 81–642 PgC (mean 314 PgC) for an RCP8.5 scenario from 2100 to 2300, and of a gain of 14 PgC to a loss of 54 PgC (mean loss of 17 PgC) for an RCP4.5 scenario over the same period.

Methane release from permafrost thaw (including abrupt thaw) under high-warming RCP8.5 scenario has been estimated at 836–2614 Tg CH_4 over the 21st century and 2800–7400 Tg CH_4 from 2100–2300 (Schneider von Deimling et al., 2015), and as 5300 Tg CH_4 over the 21st century and 16000 Tg CH_4 from 2100–2300 (Turetsky et al., 2020). For RCP4.5, these numbers are 538–2356 Tg CH_4 until 2100 and 2000-6100 Tg CH_4 from 2100–2300 (Schneider von Deimling et al., 2015), and 4100 Tg CH_4 until 2100 and 10000 Tg CH_4 from 2100–2300 (Turetsky et al., 2020).

A key uncertainty is whether permafrost carbon feedbacks scale roughly linearly with warming (Koven et

ACCEPTED VERSION SUBJECT TO FINAL EDITS

al., 2015c), or instead scale at a greater (MacDougall and Knutti, 2016b; McGuire et al., 2018) or smaller rate (e.g. CH_4 emissions estimated by Turetsky et al., (2020a)). It also remains unclear whether the permafrost carbon pool represents a coherent global tipping element of the Earth system with a single abrupt threshold (Drijfhout et al., 2015) at a given level of global warming, or a local scale tipping point without abrupt thresholds when aggregated across the pan-Arctic region as is suggested by recent model results (e.g. (Koven et al., 2015b; McGuire et al., 2018)).

In conclusion, thawing terrestrial permafrost will lead to carbon release under a warmer world (*high confidence*). However, there is *low confidence* on the timing, magnitude and linearity of the permafrost climate feedback owing to the wide range of published estimates and the incomplete knowledge and representation in models of drivers and relationships. It is projected that CO_2 released from permafrost will be 18 (3.1–41) PgC per 1°C by 2100 with the relative contribution of CO_2 vs CH_4 remaining poorly constrained. Permafrost carbon feedbacks are included among the underrepresented feedbacks quantified in Figure 5.29.

[END BOX 5.1 HERE]

5.4.4 Climate Effects on Future Ocean Carbon Uptake

5.4.4.1 Physical Drivers of Future Ocean Carbon Uptake and Storage

The principal contribution to increasing global ocean carbon is the air-sea flux of CO_2, which changes the DIC inventory (Section 5.4.2) (Arora et al., 2020). The processes that influence the variability and trends of the ocean carbon-heat nexus are assessed in Cross-Chapter Box 5.3. Climate has three important impacts on the ocean uptake of anthropogenic CO_2: (i) ocean warming reduces the solubility of CO_2, which increases pCO_2 and increases the stratification of the mixed layer with both acting as positive feedbacks weakening the ocean sink (Arora et al., 2020; Cross-Chapter Box 5.3; 9.2.1); (ii) changing the temporal and spatial characteristics of wind stress and storm alters mixing – entrainment in the mixed layer and across the bottom of the mixed layer (Bronselaer et al., 2018) and (iii) both warming and wind stress influence the large scale MOC circulation which modifies the rate of ventilation, storage or outgassing of ocean carbon in the ocean interior (Section 5.2.3.1; Gruber et al., 2019; Arora et al., 2020). The land-to-ocean riverine flux and the carbon burial in ocean sediments also play a minor role (*low confidence*) (Arora et al., 2020). Based on *high agreement* of projections by coupled climate models, there is *high confidence* that the resultant climate-carbon cycle feedbacks are positive but the extent of the weakening the ocean sink is scenario dependent (Arora et al., 2020).

Regionally, the Southern Ocean is a major sink of anthropogenic CO_2 (Figure 5.8a), although challenges in modelling its circulation and Antarctic sea ice transport (Section 3.4.1.2; Section 9.2.3.2; Section 9.3.2) generate uncertainty in the response of its sink to future carbon-climate feedbacks. Increased freshwater input may cause a slowdown of the lower overturning circulation, leading to increased Southern Ocean biological carbon storage (Ito et al., 2015); alternatively, increased winds may intensify the overturning circulation, reducing the net CO_2 sink in the Southern Ocean (Bronselaer et al., 2018; Saunders et al., 2018). On centennial timescales, there is thus *low confidence* in the overall effect of intensifying winds in the Southern Ocean on CO_2 uptake.

5.4.4.2 Biological Drivers of Future Ocean Carbon Uptake

While physical drivers control the present-day anthropogenic carbon sink, biological processes are responsible for the majority of the vertical gradient in DIC (natural carbon storage). A small fraction of the organic carbon fixed by primary production (PP) reaches the sea floor, where it can be stored in sediments on geological timescales, making the biological carbon pump (BCP) an important mechanism for very long-term CO_2 storage. Projected reductions in ocean ventilation (Section 9.2.1.4) would lengthen residence time and lead to DIC accumulating in the deep ocean due to organic carbon remineralisation.

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Since AR5 (Section 6.3.2.5.6), progress has been made in understanding the biological drivers of ocean carbon uptake in both coupled climate models and observations (SROCC Section 5.2.2.6). Here we focus on potential feedbacks between biological processes and climate. In CMIP5 models, the direction of modelled PP in response to increased atmospheric CO_2 concentration and climate warming was unclear (Taucher and Oschlies, 2011; Laufkoetter et al., 2015). This remains the case in the CMIP6 models; indeed, inter-model uncertainty has increased in CMIP6 models, compared to CMIP5. The projected global multi-model mean change in PP in 13 models run under the SSP5−8.5 scenario project is −3 ± 9% (2080–2099 mean values relative to 1870–1899 ± the inter-model standard deviation; Kwiatkowski et al., 2020). Under the low-emission, high-mitigation scenario SSP1−2.6, the global change in PP is −0.56 ± 4%. Observations in the contemporary period provide little direct constraint on the modelled responses of PP to climate change, partly due to insufficiently long records (Henson et al., 2016). However, there is some indication of an emergent constraint on changes in tropical PP based on interannual variability derived from remote sensing (Kwiatkowski et al., 2017b; Section 5.4.6).

In CMIP5 models run under RCP8.5, particulate organic carbon (POC) export flux is projected to decline by 1–12% by 2100 (Taucher and Oschlies 2011; Laufkoetter et al. 2015). Similar values are predicted in 18 CMIP6 models, with declines of 2.5–21.5% (median –14%) or 0.2–2 GtC (median –0.8 GtC) between 1900 and 2100 under the SSP5–8.5 scenario. The mechanisms driving these changes vary widely between models due to differences in parameterisation of particle formation, remineralisation and plankton community structure.

Ocean warming reduces the vertical supply of nutrients to the upper ocean due to increasing stratification (Section 9.2.1.4) but may also act to alleviate seasonal light limitation. The projected effect is to decrease PP at low latitudes and increase PP at high latitudes (Kwiatkowski et al., 2020). Future changes to dust deposition due to desertification (Mahowald et al., 2017), alterations to the nitrogen cycle (Section 5.3.3.2; SROCC Section 5.2.3.1.2), and reducing sea ice cover (Ardyna and Arrigo, 2020) all have the potential to alter PP regionally. Higher ocean temperatures tend to result in higher metabolic rates, although respiration may increase more rapidly than PP (Boscolo-Galazzo et al., 2018; Brewer, 2019; Cavan et al., 2019). Ocean warming and reduced PP are expected to result in lower zooplankton abundance, and the expansion of OMZs may reduce the ability of zooplankton to remineralise POC, thus increasing the efficiency of the BCP and forming a negative climate feedback (Cavan et al., 2017). Increased microbial respiration due to warming may result in greater quantities of organic carbon transferred into the dissolved organic carbon pool (Jiao et al., 2014; Legendre et al., 2015; Roshan and DeVries, 2017) which, while increasing the residence time of carbon in the ocean, would ultimately reduce the sedimentary burial and hence sequestration on geologic time scales (Olivarez Lyle and Lyle, 2006).

Most models project that smaller phytoplankton are favoured in future ocean conditions (*medium confidence*; Cabré et al., 2015; Fu et al., 2016; Flombaum et al., 2020) driven by warming water and/or changing nutrient availability, which would alter the magnitude and efficiency of the BCP by altering the sinking speed, respiration rate and aggregation/fragmentation of sinking particles. There is *low confidence* in the sign of the resulting feedback: regions in which small phytoplankton dominate may have a more efficient pump, although the total amount of organic carbon reaching the sea floor is lower (Herndl and Reinthaler, 2013; Bach et al., 2016; Richardson, 2019). Alternatively, an increase in small phytoplankton could result in a less efficient pump, due either to a greater fraction of PP being processed through the upper ocean microbial loop (Jiao et al., 2014) or generation of slower sinking particles (Guidi et al., 2009; Leung et al., 2021). Variable phytoplankton stoichiometry is predicted to increase the amount of carbon stored via the BCP relative to the amount of PP, so that fixed stoichiometry models (as in CMIP5) may underestimate cumulative ocean carbon uptake to 2100 by 0.5–3.5% (2–15 PgC) (RCP8.5 scenario; Kwiatkowski et al., 2018). Other climate effects such as deoxygenation or ocean acidification could also result in alterations to the magnitude and efficiency of the BCP (Krumhardt et al., 2019; Raven et al., 2021; Taucher et al., 2021).

Based on *high agreement* across multiple lines of evidence and physical understanding there is thus *high confidence* that feedbacks to climate will arise from alterations to the magnitude and efficiency of the BCP changing PP, and the depth of remineralisation. However, the complexity of the mechanisms involved in the

ACCEPTED VERSION SUBJECT TO FINAL EDITS

export and remineralisation of POC result in *low confidence* in the magnitude and sign of biological feedbacks to climate. Nevertheless, improved model representation of PP and the BCP is required (which requires better observational constraints), as the contribution of biological processes to CO_2 uptake is expected to become more significant with continued climate change (Hauck et al., 2015).

5.4.5 Carbon Cycle Projections in Earth System Models

This section summarises future projections of land and ocean carbon sinks from the latest ESMs. ESMs are the basis for century timescale projections (Chapter 4), and for detection and attribution studies (Chapter 3). These models aim to simulate the evolution of the carbon sources and sinks on land and in the ocean, in addition to the physical components of the climate system. ESMs include interactions between many of the processes and feedbacks described in Sections 5.4.1 to 5.4.4.

ESMs are now integral to the coupled model intercomparison project. Model output data from CMIP5 was analysed in the AR5, while data from CMIP6 forms the basis for the analysis presented in this subsection. The CMIP5 ESMs discussed in AR5 (WGI, Section 6.4.2) produced a wide range of projections of future CO_2 (Friedlingstein et al., 2014) primarily associated with different magnitudes of carbon-climate and carbon-concentration feedbacks (Arora et al., 2013), but also exacerbated by differences in the simulation of the net carbon release from land-use change (Brovkin et al., 2013). A key deficiency of almost all CMIP5 ESMs was the neglect of nutrient limitations on CO_2-fertilisation of land plant photosynthesis (Zaehle et al., 2015) (see Section 5.4.1).

Some CMIP6 models considered in this report now include nitrogen limitations on land vegetation growth, along with many other added processes compared to CMIP5. Table 5.4 summarises characteristics of the land and ocean carbon cycle models used in CMIP6 ESMs (Arora et al., 2020). In CMIP6, most ocean carbon cycle models (8 of 11) track three or more limiting nutrients (most often nitrogen, phosphorus, silicon, iron), and represent two or more phytoplankton types. More than half of the land carbon cycle models (6 of 11) now include an interactive nitrogen cycle, and almost half (5 of 11) represent forest fires. However, even for CMIP6, very few models explicitly represent vegetation dynamics (3 of 11) or permafrost carbon (2 of 11). Despite these remaining limitations, the carbon cycle components of CMIP6 represent an advance on those in CMIP5 as they represent additional important processes (e.g. nitrogen-limitations on the land carbon sink, iron-limitations on ocean ecosystems).

[START TABLE 5.4 HERE]

Table 5.4: Properties of the CMIP6 Earth system models (ESMs), focussing on the land and ocean carbon cycle components of these models (Arora et al., 2020). Characteristics listed under each ESM are: number of vegetation carbon pools (Veg C pools), number of soil and litter carbon pools (Dead C pools), number of Plant Functional Types (PFTs), whether forest fire is represented (Fire), whether vegetation dynamics is represented (Dynamic Veg), whether permafrost carbon is represented (Permafrost C), whether the nitrogen cycle is represented (Nitrogen cycle), the number of phytoplankton types (Phytoplankton), the number of zooplankton types (Zooplankton), and the list of ocean nutrients represented (Nutrients).

ESMs can be driven by anthropogenic CO_2 emissions ('emissions-driven' runs), in which case atmospheric CO_2 concentration is a predicted variable; or by prescribed time-varying atmospheric concentrations ('concentration-driven' runs). In concentration-driven runs, simulated land and ocean carbon sinks respond to the prescribed atmospheric CO_2 and resulting changes in climate, but do not feed back through changes in the atmospheric CO_2 concentration. Concentration-driven runs are used to diagnose the carbon emissions consistent with the SSPs and other prescribed concentration scenarios (Section 5.5). In this subsection we specifically analyse results from concentration-driven ESM projections.

5.2.1.1 Evaluation of the Contemporary Carbon Cycle in Concentration-Driven Runs

Models need to be compared to as wide an array of observational benchmarks as possible in order to have confidence in their projections. This is particularly the case for highly-uncertain land carbon cycle feedbacks (Arora et al., 2013; Friedlingstein et al., 2014b). Land models within ESMs can be compared to multiple different datasets of processes such as gross carbon uptake, physical predictions such as leaf area and carbon stocks which influence carbon fluxes and are diagnostic of carbon turnover times, as well as linkages between carbon and water cycles and other aspects of the terrestrial carbon cycle. To provide these multiple orthogonal constraints, a model benchmarking system, the international land model benchmarking (ILAMB), has been developed (Collier et al., 2018).

Figure 5.22 shows an overview set of land (Figure 5.22a) and ocean (Figure 5.22b) benchmarks applied to both the CMIP5 and CMIP6 historical simulations. There is good evidence of an improvement in model performance from CMIP5 (in yellow) to CMIP6 (in green), in both the land and ocean, based on these benchmarks. The mean of the CMIP6 land models outperform or perform equivalently to the mean of the CMIP5 land models on all available metrics.

[START FIGURE 5.22 HERE]

Figure 5.22: Overview scores for CMIP5 (left hand side of table) and CMIP6 (right hand side of table) Earth system models (ESMs), for multiple benchmarks against different datasets. (a) Benchmarking of ESM land models, (b) benchmarking of ocean models. Scores are relative to other models within each benchmark row, with positive scores indicating a better agreement with observations. Models included are only those from institutions that participated in both CMIP5 and CMIP6 carbon cycle experiments, in order to trace changes from one ensemble to the next. CMIP5 models are labels in yellow and CMIP6 in green, with the multi-model ensemble means labelled in white. Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

5.4.5.1 Evaluation of Historical Carbon Cycle Simulations in Concentration-Driven Runs

This section evaluates concentration-driven historical simulations of changes in land and ocean cumulative carbon uptake, against observation-based estimates from GCP (Le Quéré et al., 2018a). For each model, common historical land-use changes were prescribed (Jones et al., 2016a).

Figure 5.23 shows global annual mean values from CMIP6 concentration-driven runs for 1850 to 2014. The ocean carbon cycle models reproduce historical carbon uptake well, with the model range for the global ocean carbon sink in 2014 (2.3–2.7 GtC yr^{-1}) clustering around the central GCP estimate of 2.6 ± 0.5 GtC yr^{-1}. Simulated cumulative ocean carbon uptake (1850–2014) ranges from 110 to 166 GtC, with a model mean of 131 ± 17 PgC which is lower than the GCP estimate of 150 ± 25 GtC (Figure 5.23a). This suggests that CMIP6 models may slightly underestimate historical ocean carbon uptake (Watson et al., 2020).

The land carbon cycle components of historical ESM simulations show a larger range, with simulated cumulative land carbon uptake (1850–2014) spanning the range from –47 to +21 GtC, compared to the GCP estimate of –12 ± 50 GtC (Figure 5.22b). This range is due in part to the complications of simulating the difference between carbon uptake by intact ecosystems and the direct release of carbon due to land-use change (Hajima et al., 2020a). There is *high confidence* that the land continues to dominate the overall uncertainty in the projected response of the global carbon cycle to climate change.

[START FIGURE 5.23 HERE]

Figure 5.23: CMIP6 Earth system model (ESM) concentration-driven historical simulations for 1850 to 2014, compared to observation-based estimates from the global carbon project (GCP). Panel (a) cumulative ocean carbon uptake from 1850 (PgC); (b) cumulative land carbon uptake from 1850 (PgC). Only models that simulate both land and ocean carbon fluxes are shown here. Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

[END FIGURE 5.23 HERE]

5.4.5.2 Evaluation of Latitudinal Distribution of Simulated Carbon Sinks

This distinction between the relatively high fidelity with which the ocean carbon sink is simulated, and the much wider range of simulations of the land carbon sink, is also evident in the zonal distribution of the sinks (Figure 5.24). We compare the ESM simulations to estimates from three atmospheric inversion models: CAMS (Chevallier et al., 2005), CT 2017 (Peters et al., 2007) and MIROC-ATM4 (Saeki and Patra, 2017). The ocean carbon cycle components of CMIP6 ESMs are able to simulate the tropical CO_2 source and mid-latitude CO_2 sink, with relatively small model spread (Figure 5.24a). The CMIP6 ensemble (red wedge) simulates a larger ocean carbon sink at 50°N and a weaker sink in the Southern Ocean, than the inversion estimate, but with some evidence of a reduction in these residual errors compared to CMIP5 (blue wedge). The spread in inversion fluxes arises primarily from differences in the atmospheric CO_2 measurement networks and from transport model uncertainties.

It has been previously noted that AR5 models tended to overestimate land-uptake in the tropics and underestimate uptake in the northern mid-latitudes, compared to inversion estimates. The inclusion of nitrogen limitations on CO_2-fertilisation within CMIP6 models was expected to reduce this discrepancy (Anav et al., 2013). There is indeed some evidence that the CMIP6 ensemble (red wedge in Figure 5.24b) captures the northern land carbon sink more clearly than CMIP5 (blue wedge in Figure 5.24b), but there remains a tendency for the ESMs to place more of the global land carbon sink in the tropics than the mid-latitudes, compared to the inversion estimates. Based on a consistent signal across CMIP6 ESMs, there is *medium confidence* that land carbon cycle models continue to underestimate the northern hemisphere land carbon sink, when compared to estimates from atmospheric inversion (Ciais et al., 2019).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

[START FIGURE 5.24 HERE]

Figure 5.24: Comparison of modelled zonal distribution of contemporary carbon sinks against atmospheric inversion estimates for 2000–2009, (a) ocean carbon uptake; (b) net land uptake. Latitude runs from 90°S (i.e. –90°N) to 90°N. Positive uptake represents a carbon sink to ocean/land while negative uptake represents a carbon source. The land uptake is taken as Net Biome Productivity (NBP) and so includes net land-use change emissions. The bands show the mean ±1 standard deviation across the available inversions (black bands, 3 models), CMIP5 Earth system models (ESMs) (blue bands, 12 models for the ocean, 12 models for the land), and CMIP6 ESMs (red bands, 11 models for ocean, 10 models for land). Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

[END FIGURE 5.24 HERE]

5.4.5.3 Coupled Climate-Carbon Cycle Projections

Land and ocean carbon uptake are driven primarily by increases in atmospheric CO_2 (Figure 5.25). As a result, the evolution of land and ocean carbon sinks differs significantly between the SSP scenarios. Under scenarios which have greater increases in atmospheric CO_2 (such as SSP5–8.5 and SSP3–7.0) the absolute values of the sinks are larger, but the fraction of implied emissions taken-up by the sinks declines through the 21st century. By contrast, scenarios that assume CO_2 stabilisation in the 21st century (such as SSP1–2.6 or SSP2–4.5), have smaller absolute sinks but these sinks take-up an increasing fraction of the implied emissions (Figure 5.25d). These general principles apply to both the ocean and land carbon sinks.

The concentration-driven CMIP6 ESMs agree well on the evolution of the global ocean carbon sink through the 21st century for four SSP scenarios (Figure 5.26b). The 5-year ensemble mean ocean sink declines to 0.6 ± 0.2 GtC yr^{-1} by 2100 under SSP1–2.6, and peaks around 2080 at 5.4 ± 0.4 GtC yr^{-1} under SSP5–8.5. Cumulative ocean carbon uptake from 1850 is projected to saturate at approximately 290 ± 30 GtC under SSP1–2.6, and to reach 520 ± 40 GtC by 2100 under SSP5–8.5 (Figure 5.25e).

The ensemble mean changes in land and ocean sinks are qualitatively similar, but the land shows much higher interannual variability in carbon uptake (Figure 5.25c) and also a much larger spread in the model projections of cumulative land carbon uptake (Figure 5.25f). The 5-year ensemble mean net land carbon sink is projected to decline to 0.4 ± 1.0 GtC yr^{-1} by 2100 under SSP1–2.6, and to reach around 5.6 ± 3.7 GtC yr^{-1} under SSP5–8.5 (Figure 5.25b). Cumulative net land carbon uptake from 1850 is projected to saturate at approximately 150 ± 35 GtC under SSP1–2.6, and to reach 310 ± 130 GtC by 2100 under SSP5–8.5. Significant uncertainty remains in the future of the global land carbon sink, but there has been a notable reduction in the model spread from CMIP5 to CMIP6.

[START FIGURE 5.25 HERE]

Figure 5.25: Modelled evolution of the global land and ocean carbon sinks for 1850 to 2100 in concentration-driven CMIP6 Earth system model (ESM) scenario runs (SSP1–2.6: blue; SSP2–4.5: skyblue; SSP3–7.0: yellow; SSP5–8.5: red): (a) prescribed atmospheric CO_2 concentrations; (b) 5-year running mean ocean carbon sink (GtC yr^{-1}); (c) 5-year running mean net land carbon sink (GtC yr^{-1}); (d) inferred cumulative sink fraction of emissions from 1850; (e) change in ocean carbon storage from 1850 (GtC); (f) change in land carbon storage from 1850 (GtC). Thick lines represent the ensemble mean of the listed ESM runs, and the error bars represents ± one standard deviation about that mean. The grey wedges represent estimates from the global carbon project (GCP), assuming uncertainties in the annual mean ocean and net land carbon sinks of 0.5 GtC yr^{-1} and 1 GtC yr^{-1} respectively, and uncertainties in the changes in carbon stores (ocean, land and cumulative total emissions) of 25 GtC. The net land carbon sink is taken as net biome productivity (NBP) and so includes any modelled net land-use change emissions. Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

[END FIGURE 5.25 HERE]

Geographical patterns of carbon changes for four SSP scenarios are shown in Figure 5.26, with cleared areas (no diagonal lines) showing agreement on the sign of the change by at least 80% of the models. In all scenarios the ocean sink is strongest in the Southern Ocean and North Atlantic. The land carbon sink occurs primarily where there are present-day forests. In the mid- and high northern latitudes, a carbon sink is projected as a result of the combined impacts of increasing CO_2 and warming (see Section 5.4.5.5). Changes in land carbon storage in the tropics also depend strongly on the assumed rate of deforestation which varies in magnitude across the SSPs, from relatively low rates in SSP1–2.6 to relatively high rates in SSP3–7.0.

[START FIGURE 5.26 HERE]

Figure 5.26: Maps of net carbon changes under four Shared Socioeconomic Pathway (SSP) scenarios, as evaluated from nine CMIP6 Earth system models. Uncertainty is represented using the simple approach (see Cross-Chapter Box Atlas.1 for more information): No overlay indicates regions with high model agreement, where ≥80% of models agree with the ensemble mean on the sign of change; diagonal lines indicate regions with low model agreement, where <80% of models agree with the ensemble mean on the sign of change. On land, this is calculated as the time integral of NBP, for the ocean it is the time-integral of air-sea CO_2 gas flux anomalies relative to the pre-industrial. Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

[END FIGURE 5.26 HERE]

In summary, oceanic and terrestrial carbon sinks are projected to continue to grow with increasing atmospheric concentrations of CO_2, but the fraction of emissions that is taken up by land and ocean is expected to decline as the CO_2 concentration increases (*high confidence*). In the ensemble mean, ESMs suggest approximately equal global land and ocean carbon uptake for each of the SSP scenarios. However, the range of model projections is much larger for the land carbon sink. Despite the wide range of model responses, uncertainty in atmospheric CO_2 by 2100 is dominated by future anthropogenic emissions rather than carbon-climate feedbacks (*high confidence*).

5.4.5.4 Linear Feedback Analysis

In order to diagnose the causes of the varying time-evolution of carbon sinks, the traditional linear feedback approach is adopted (Friedlingstein et al., 2003), as used previously to analyse C^{4}MIP (Friedlingstein et al., 2006) and CMIP5 models (Arora et al., 2013). Changes in land carbon storage (ΔC_L) and changes in ocean carbon storage (ΔC_o) are decomposed into contributions arising from warming (ΔT) and increases in CO_2 (ΔCO_2):

$$\Delta C_L = \beta_L \, \Delta CO_2 + \gamma_L \, \Delta T$$

$$\Delta C_o = \beta_o \, \Delta CO_2 + \gamma_o \, \Delta T$$

where β_L (β_o) and γ_L (γ_o) are coefficients that represent the sensitivity of land (ocean) carbon storage to changes in CO_2 and global mean temperature respectively. This feedback formalism is one of several that have been proposed for analysing climate-carbon cycle feedbacks (Lade et al., 2018).

This quasi-equilibrium framework is scenario dependent because of the timescales associated with land and ocean carbon uptake, as discussed in AR5 (WGI, Box 6.4). However, it is retained here for traceability with AR5. This approach has been used to define a number of emergent constraints on carbon cycle feedbacks (Section 5.4.6) and to reconstruct the transient climate response to emissions (TCRE) (Jones and Friedlingstein, 2020), as in Section 5.5. In order to minimise the confounding effect of the scenario

ACCEPTED VERSION SUBJECT TO FINAL EDITS

dependence, β and γ values are diagnosed from idealised runs in which a 1% per year increase in atmospheric CO_2 concentration is prescribed, as for AR5 (WGI, Box 6.4) (Arora et al., 2013). Values of β are calculated from 'biogeochemical' runs in which the prescribed CO_2 increases do not affect climate, and these are then used to isolate γ values in fully-coupled runs in which both climate and CO_2 change (Friedlingstein et al., 2003).

Table 5.5 shows the global land and global ocean values of β and γ for each of the CMIP6 ESMs (Arora et al., 2020). Also shown in the last two rows are the ensemble mean and standard deviation across the ensemble, for CMIP6 and CMIP5. In both ensembles, the largest uncertainties are in the sensitivity of land carbon storage to CO_2 (β_L) and the sensitivity of land carbon storage to temperature (γ_L). The more widespread modelling of nitrogen limitations in CMIP6 was expected to lead to reductions in both of these feedback parameters. There is indeed some evidence for that with ensemble mean γ_L moving from –58 ± 38 GtC K^{-1} to –33 ± 33 GtC K^{-1}. Between CMIP5 and CMIP6, there are also reductions in ensemble mean β_o (0.82 to 0.77 GtC ppm^{-1}), β_L (0.93 to 0.89 GtC K^{-1}) and γ_o (–17.3 to –16.9 GtC K^{-1}), but these are progressively less significant compared to the model spread in each case.

[START TABLE 5.5 HERE]

Table 5.5: Diagnosed global feedback parameters for CMIP6 ESMs based on 4 x CO_2 runs (Arora et al., 2020). The last two rows show the mean and standard deviation cross the CMIP6 and CMIP5 models, respectively.

[END TABLE 5.5 HERE]

In these idealised 1% per year CO_2 runs, the CMIP6 models show reasonable agreement on the patterns of carbon uptake and also on the separate impacts of CO_2 increase and climate change (Figure 5.27). For the ensemble mean, increasing atmospheric CO_2 increases carbon uptake by the oceans, especially in the

Southern Ocean and the North Atlantic Ocean; and on the land, especially in tropical and boreal forests (*β,* Figure 5.27a). Climate change further enhances land carbon storage in the boreal zone but has a compensating negative impact on the carbon sink in tropical and subtropical lands, and in the North Atlantic

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Ocean (γ, Figure 5.27b). Overall, the ensemble mean of the CMIP6 ESMs models indicates increasing carbon storage with CO_2 in almost all locations (Figure 5.27c).

[START FIGURE 5.27 HERE]

Figure 5.27: Maps of carbon-concentration and carbon-climate feedback terms, as well as net carbon changes under the idealised 1% per year CO_2 scenario, as evaluated from CMIP6 Earth system models (ESMs). Shown are the model means from nine CMIP6 ESMs. Uncertainty is represented using the simple approach (see Cross-Chapter Box Atlas.1 for more information): No overlay indicates regions with high model agreement, where ≥80% of models agree with the ensemble mean on the sign of change; diagonal lines indicate regions with low model agreement, where <80% of models agree with the ensemble mean on the sign of change. Also shown are zonal-mean latitude profiles of land (green) and ocean (blue) feedbacks. On the land, the zonal mean feedback for the mean of the ensemble of models that include nitrogen is shown as dashed lines, and carbon-only models as dash-dotted lines, and the carbon-climate feedback from one permafrost-carbon enabled ESM is shown as a dotted line carbon changes are calculated as the difference between carbon stocks at different times on land and for the ocean as the time integral of atmosphere-ocean CO_2 flux anomalies relative to the pre-industrial. The denominator for gamma here is the global mean surface air temperature. Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

[END FIGURE 5.27 HERE]

5.4.6 Emergent constraints to reduce uncertainties in projections

Emergent constraints are based on relationships between observable aspects of the current or past climate (such as trends or variability), and uncertain aspects of future climate change (such as the strength of particular feedbacks). These relationships are evident across an ensemble of models. When combined with an observational estimate of the trend or variability in the real climate, such emergent relationships can yield 'emergent constraints' on future climate change (Hall et al., 2019). At the time of the AR5 (WGI, 9.8.3), there had been relatively few applications of the technique to constrain carbon cycle sensitivities, but there have been many studies published since (see for example summary in Cox, (2019)). Figure 5.28 shows some key published emergent constraints on the carbon cycle in ESMs.

[START FIGURE 5.28 HERE]

Figure 5.28: Examples of emergent constraints on the carbon cycle in Earth system models (ESMs), reproduced from previously published studies: (a) projected global mean atmospheric CO_2 concentration by 2060 under the RCP8.5 emissions scenario against the simulated CO_2 in 2010 (Friedlingstein et al., 2014b; Hoffman et al., 2014); (b) sensitivity of tropical land carbon to warming (γ_{LT}) against the sensitivity of the atmospheric CO_2 growth-rate to tropical temperature variability (Cox et al., 2013b; Wenzel et al., 2014); (c) sensitivity of extratropical (30°N–90°N) gross primary production to a doubling of atmospheric CO_2 against the sensitivity of the amplitude of the CO_2 seasonal cycle at Kumkahi, Hawaii to global atmospheric CO_2 concentration (Wenzel et al., 2016); (d) change in high-latitude (30°N–90°N) gross primary production versus trend in high-latitude leaf area index or 'greenness' (Winkler et al., 2019); (e) sensitivity of the primary production of the Tropical ocean to climate change versus its sensitivity to ENSO-driven temperature variability (Kwiatkowski et al., 2017); (f) global ocean carbon sink in the 2090s versus the current-day carbon sink in the Southern Ocean. In each case, a red-dot represents a single ESM projection, the grey bar represents the emergent relationship between the y-variable and the x-variable, the blue bar represents the observational estimate of the x-axis variable, and the green bar represents the resulting emergent constraint on the y-axis variable. The thicknesses represent ± one standard error in each case. Figure after Cox, (2019). Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

5.4.7 Climate Feedbacks from CH4 and N2O

Sources and sinks of CH_4 and N_2O respond both directly and indirectly to atmospheric CO_2 concentration and climate change, and thereby give rise to additional biogeochemical feedbacks in the climate system, which may amplify or attenuate climate-carbon cycle feedbacks (Gasser et al., 2017; Lade et al., 2018; Denisov et al., 2019). Many of these of feedbacks are only partially understood, and thus were only partially addressed in AR5 (WGI, Sections 6.3.3, 6.3.4, 6.4.7). Since AR5, a growing body of estimates from ESMs, as well as independent modelling and observation-based studies, enable improved estimates of the associated feedbacks.

The goal of this section is to assess the climate feedback parameters α, as it is defined in Section 7.4.1.1, for CH_4 and N_2O biogeochemical feedbacks. The strength of the feedbacks is estimated in a linear framework (Gregory et al., 2009), using the radiative forcing equations for CO_2, CH_4 and N_2O (Etminan et al., 2016). In addition to estimates from ESMs, the feedback parameter α is estimated from independent estimates of surface emission climate sensitivities and atmospheric box models, following (Arneth et al., 2010; Thornhill et al., 2020). These assessed feedback parameters are used in Section 7.4.2.5.

CH_4 feedbacks may arise from changing wetland emissions (including rice farming) and from sources that are expected to grow under climate change (e.g. related to permafrost thaw, fires, and freshwater bodies). CH_4 emissions from wetlands and landfills generally increase with warming due to enhanced decomposition with higher temperatures, thereby potentially providing a positive CH_4 feedback on climate (Dean et al., 2018). The contribution of wetlands to interannual variability of atmospheric CH_4 is shaped by the different impacts of temperature and precipitation anomalies on wetland emissions (e.g. during El Niño episodes) and therefore the relationship between climate anomalies and the wetland contribution to the CH_4 growth rate is complex (Pison et al., 2013; Nisbet et al., 2016; Zhang et al., 2020b). As assessed by SROCC (IPCC, 2019b), there is *high agreement* across model simulations that wetlands CH_4 emissions will increase in the 21st century, but *low agreement* in the magnitude of the change (Denisov et al., 2013; Shindell et al., 2013a; Stocker et al., 2013a; Zhang et al., 2017; Koffi et al., 2020). Climate change increases wetland emissions (Gedney, 2004; Volodin, 2008; Ringeval et al., 2011; Denisov et al., 2013; Shindell et al., 2013a; Gedney et al., 2019) and gives rise to an estimated wetland CH_4-climate feedback of 0.03 ± 0.01 W m^{-2} $°C^{-1}$ (mean ± 1 standard deviation; *limited evidence, high agreement*) (Arneth et al., 2010; Shindell et al., 2013b; Stocker et al., 2013a; Zhang et al., 2017). The effect of rising CO_2 on productivity, and therefore on the substrate for methanogenesis, can further increase the projected increase in wetland CH_4 emissions (Ringeval et al., 2011; Melton et al., 2013). Model projections accounting for the combined effects of CO_2 and climate change suggest a potentially larger climate feedback (0.01–0.16 W m^{-2} $°C^{-1}$; *limited evidence, limited agreement*) (Gedney et al., 2019; Thornhill et al., 2020). Methane release from wetlands depends on the nutrient availability for methanogenic and methanotrophic microorganisms that can further modify this feedback (Stepanenko et al., 2016; Donis et al., 2017; Beaulieu et al., 2019). Methane emissions from thermokarst ponds and wetlands resulting from permafrost thaw, is estimated to contribute an additional CH_4-climate feedback of 0.01 [0.003–0.04, 5–95th percentile range] W m^{-2} $°C^{-1}$ (*limited evidence, moderate agreement*).

Methane release from wildfires may increase by a up to a factor of 1.5 during the 21st century (Eliseev et al., 2014a, 2014b; Kloster and Lasslop, 2017). However, given the contemporary estimate for CH_4 from wildfires of no more than 16 $TgCH_4$ yr^{-1} (van der Werf et al., 2017; Saunois et al., 2020), this feedback is small, adding no more than 40 ppb to the atmospheric CH_4 by the end of the 21st century (*medium confidence*). Methane emissions from pan-Arctic freshwater bodies is also estimated to increase by 16 $TgCH_4$ yr^{-1} in the 21st century (Tan and Zhuang, 2015). Emissions from subsea and permafrost methane hydrates are not expected to change substantially in the 21st century (Section 5.4.8).

Land biosphere models show *high agreement* that long-term warming will increase N_2O release from terrestrial ecosystems (Xu-Ri et al., 2012; Stocker et al., 2013b; Zaehle, 2013a; Tian et al., 2019). A positive land N_2O climate feedback is consistent with paleo-evidence based on reconstructed and modelled emissions

ACCEPTED VERSION SUBJECT TO FINAL EDITS

during the last deglacial period (Schilt et al., 2014; Fischer et al., 2019b; Joos et al., 2020). The response of terrestrial N_2O emissions to atmospheric CO_2 increase and associated warming is dependent on nitrogen availability (van Groenigen et al., 2011; Butterbach-Bahl et al., 2013; Tian et al., 2019). Model-based estimates do not account for the potentially strong emission increases in Boreal and Arctic ecosystems associated with future warming and permafrost thaw (Elberling et al., 2010; Voigt et al., 2017). There is *medium confidence* that the land N_2O climate feedback is positive, but *low confidence* in the magnitude (0.02 ± 0.01 W m^{-2} °C^{-1}).

Climate change will also affect N_2O production in the ocean (Codispoti, 2010; Freing et al., 2012; Bopp et al., 2013; Rees et al., 2016; Breider et al., 2019). Model projections in the 21st century show a 4–12% decrease in ocean N_2O emissions under RCP8.5 due to a combination of factors including increased ocean stratification, decreases in ocean productivity, and the impact of increasing atmospheric N_2O abundance on the air-sea flux, corresponding to an ocean N_2O climate feedback of –0.008 ± 0.002 W m^{-2} °C^{-1} (*high agreement, limited evidence*) (Martinez-Rey et al., 2015; Landolfi et al., 2017; Battaglia and Joos, 2018). On millennial timescales, the ocean N_2O climate feedback may be positive, owing to ocean deoxygenation and long-term increases in remineralisation (Battaglia and Joos, 2018b).

Based-on these studies, there is medium confidence that the combined climate feedback parameter for CH_4 and N_2O is positive, but there is low confidence in the magnitude of the estimate (0.05 (0.02–0.09) W m^{-2} °C^{-1}, 5–95th percentile range).

5.4.8 Combined Biogeochemical Climate Feedback

This section assesses the magnitude of the combined biogeochemical feedback in the climate system (Figure 5.29) by integrating evidence from: carbon-cycle projections represented in Earth system models (Section 5.4.5.5), independent estimates of CO_2 emissions due to permafrost thaw (Box 5.1) and fire (Section 5.4.3.2), natural CH_4 and N_2O emissions (Section 5.4.7), and aerosol and atmospheric chemistry (Section 6.3.6). We derive a physical climate feedback parameter α, as defined in Section 7.4.1.1, for CO_2-based feedbacks using the linear framework proposed by Gregory et al. (2009), using the radiative forcing equations for CO_2 (Etminan et al., 2016).

[START FIGURE 5.29 HERE]

Figure 5.29: Estimates of the biogeochemical climate feedback parameter (α). The parameter α (W m^{-2} °C^{-1}) for a feedback variable x is defined as $\alpha_x = \frac{\partial N}{\partial x}\frac{dx}{dT}$ where $\frac{\partial N}{\partial x}$ is the change in TOA energy balance in response to a change in x induced by a change in surface temperature (T), as in Section 7.4.1.1. (a) Synthesis of biogeochemical feedbacks from panels (b) and (c). Red (blue) bars correspond to positive (negative) feedbacks increasing (decreasing) radiative forcing at the top of the atmosphere. Bars denote the mean and the error bar represents the 5–95th percentile range of the estimates; (b) carbon-cycle feedbacks as estimated by coupled carbon-cycle climate models in the CMIP5 (Arora et al., 2013) and CMIP6 (Arora et al., 2020) ensembles, where dots represent single model estimates, and filled (open) circles are those estimates which do (not) include the representation of a terrestrial nitrogen cycle; (c) Estimates of other biogeochemical feedback mechanisms based on various modelling studies. Dots represent single estimates, and coloured bars denote the mean of these estimates with no weighting being made regarding the likelihood of any single estimate, and error bars the 5–95th percentile range derived from these estimates. Results in panel (c) have been compiled from (a) Section 5.4.3.2 (Eliseev et al., 2014a; Harrison et al., 2018); (b) Section 5.4.3.3 (Schneider von Deimling et al., 2012; Burke et al., 2013, 2017b, Koven et al., 2015c, 2015b; MacDougall and Knutti, 2016b; Gasser et al., 2018; Kleinen and Brovkin, 2018), where the estimates from Burke et al. have been constrained as assessed in their study (c) Section 5.4.7 (Schneider von Deimling et al., 2012, 2015; Koven et al., 2015c; Turetsky et al., 2020); (d) Section 5.4.7 (Arneth et al., 2010; Denisov et al., 2013; Shindell et al., 2013a; Stocker et al., 2013a; Zhang et al., 2017); (f) Section 5.4.7 (Xu-Ri et al., 2012; Zaehle, 2013; Stocker et al., 2013; Tian et al., 2019); (g) Section 5.4.7 (Martinez-Rey et al., 2015; Landolfi et al., 2017; Battaglia and Joos, 2018). (h) Section 6.3, Table 6.9 mean and the 5–95th percentile range the assessed feedback parameter. Further details on data

ACCEPTED VERSION SUBJECT TO FINAL EDITS

sources and processing are available in the chapter data table (Table 5.SM.6).

[END FIGURE 5.29 HERE]

The climate feedback parameter for CO_2 (–1.13 ± 0.45 W m^{-2} °$C^{-1,}$ mean and 1 standard-deviation range) is dominated by the contribution of the CO_2-induced increase of ocean and land carbon storage (–1.46 ± 0.41 W m^{-2} °C^{-1}, corresponding to a β_{L+O} of 1.66 ± 0.31 PgC ppm^{-1}), with smaller contributions from the carbon cycle's response to climate (0.24 ± 0.17 W m^{-2} °C^{-1}, corresponding to γ_{L+O} of –50 ± 34 PgC °C^{-1}), and emissions from permafrost thaw (0.09 [0.02–0.20] W m^{-2} °C^{-1}, corresponding to γ of –18 [3–41] PgC °C^{-1}, mean and 5–95th percentile range) (Figure 5.29a). This estimate does not include an estimate of the fire-related CO_2 feedback (range: 0.01–0.06 W m^{-2} °C^{-1}), as only limited evidence was available to inform its assessment. The sum (mean and 5–95th percentile range) of feedbacks from natural emissions of CH_4 including permafrost thaw, and N_2O (0.05 [0.02–0.09] W m^{-2} °C^{-1}), and feedbacks from aerosol and atmospheric chemistry (–0.20 [–0.41 to 0.01] W m^{-2} °C^{-1}) leads to an estimate of the non-CO_2 biogeochemical feedback parameter of –0.15 [–0.36 to 0.06] W m^{-2} °C^{-1}. There is *low confidence* in the estimate of the non-CO_2 biogeochemical feedbacks, due to the large range in the estimates of α for some individual feedbacks (Figure 5.29c), which can be attributed to the diversity in how models account for these feedbacks, limited process-level understanding, and the existence of known feedbacks for which there is not sufficient evidence to assess the feedback strength.

CO_2 and non-CO_2 biogeochemical feedbacks are an important component of the assessment of TCRE and the remaining carbon budget (Section 5.5). The feedbacks of the carbon cycle of CO_2 and climate are implicitly taken account in the TCRE assessment, because they are represented in the various underlying lines of evidence. Other feedback contributions, such as the non-CO_2 biogeochemical feedback, can be converted into a carbon-equivalent feedback term (γ; Section 5.4.5.5, 7.6) by reverse application of the linear feedback approximation (Gregory et al., 2009). The contributions of non-CO_2 biogeochemical feedbacks combine to a linear feedback term of 30 ± 27 PgCeq °C^{-1} (1 standard deviation range, 111 ± 98 Gt CO_2eq °C^{-1}), including a feedback term of –11 (–18 to –5) PgCeq °C^{-1} (5th–95th percentile range, –40 (–62 to –18) Gt CO_2eq °C^{-1}) from natural CH_4 and N_2O sources. The biogeochemical feedback from permafrost thaw leads to a combined linear feedback term of –21 ± 12 PgCeq °C^{-1} (1 standard deviation range –77 ± 44 Gt CO2eq °C^{-1}). For the integration of these feedbacks in the assessment of the remaining carbon budget (Section 5.5.2), two individual non-CO_2 feedbacks (tropospheric ozone, and methane lifetime) are captured in the AR6-calibrated emulators (Box 7.1). Excluding those two contributions, the resulting combined linear feedback term for application in Section 5.5.2 is assessed at a reduction of 7 ± 27 PgCeq °C^{-1} (1 standard deviation range, –26 ± 97 PgCeq °C^{-1}). For the same reasons as for the feedback terms expressed in W m^{-2} °C^{-1} (see above), there is overall *low confidence* in the magnitude of these feedbacks.

5.4.9 Abrupt Changes and Tipping Points

The applicability of the linear feedback framework (Section 5.4.5.5) suggests that large-scale biogeochemical feedbacks are approximately linear in the forcing from changes in CO_2 and climate. Nevertheless, regionally the biosphere is known to be capable of producing abrupt changes or even 'tipping points' (Higgins and Scheiter, 2012; Lasslop et al., 2016). Abrupt change is defined as a change in the system that is substantially faster than the typical rate of the changes in its history (Chapter 1, Section 1.4.5). A related matter is a tipping point: a critical threshold beyond which a system reorganizes, often abruptly and/or irreversibly. Possible abrupt changes in the Earth system include those related to ecosystems and biogeochemistry (Lenton et al., 2008; Steffen et al., 2018): tropical and boreal forest dieback; and release of greenhouse gases from permafrost and methane clathrates (Table 5.6). It is not currently possible to carry out a full assessment of proposed abrupt changes and tipping points in the biogeochemical cycles. In this section we therefore focus instead on estimating upper limits on the possible impact of abrupt changes on the evolution of atmospheric GHGs out to 2100, for comparison to the impact of direct anthropogenic emissions.

ACCEPTED VERSION SUBJECT TO FINAL EDITS

[START TABLE 5.6 HERE]

Table 5.6: Examples of possible biogeochemical abrupt changes and tipping points in the Earth system. The fourth and sixth comments provide upper estimates of the impact of each example on the evolution of atmospheric GHGs in the 21st century. These upper estimates are therefore *very unlikely* but provide a useful comparison to the impact of direct anthropogenic emissions (currently 2.5 ppm yr^{-1}).

Abrupt change/Tipping point	Key region(s)	Probability to occur in the 21st century	Maximum carbon dioxide or methane release in the 21st century	Principal development timescale	Maximum CO_2 or CH_4 rate of change over the 21st century	(Ir)reversibility
Tropical forests dieback (Section 5.4.9.1.1)	Amazon watershed	low	<200 PgC as CO_2 (Section 5.4.8.1.1; *medium confidence*)	multi-decadal	CO_2: <0.5 ppm yr^{-1}	irreversible at multi-decadal scale (*medium confidence*)
Boreal forests dieback (Section 5.4.9.1.1, 5.4.3.2)	boreal Eurasia and North America	low	<27 Pg (Section 5.4.8.1.1; *medium confidence*)	multi-decadal	small (*low confidence*)	irreversible at multi-decadal scale (*medium confidence*)
Biogenic emissions from permafrost thaw (Section 5.4.9.1.2)	pan-Arctic	high	up to 240 PgC of CO_2 and up to 5300 Tg of CH_4 (Section 5.4.8.1.2; *low confidence*)	multi-decadal	CO_2: ≤1 ppm yr^{-1} CH_4: ≤10 ppb yr^{-1}	irreversible at centennial timescales (*high confidence*)
Methane release from clathrates (Section 5.4.9.1.3)	oceanic shelf	very low	*very likely* small (Section 5.4.9.1.3)	multi-millennium	CH_4: ≤0.2 ppb yr^{-1}	irreversible at multi-millennium timescales (*medium confidence*)

[END TABLE 5.6 HERE]

ACCEPTED VERSION SUBJECT TO FINAL EDITS

5.4.9.1 Assessment of biogeochemical tipping points

5.4.9.1.1 Forest Dieback

Published examples of abrupt biogeochemical changes in models include tropical rain forest dieback (Cox et al., 2004; Jones et al., 2009; Brando et al., 2014; Le Page et al., 2017; Zemp et al., 2017), and temperate and boreal forest dieback (Joos et al., 2001; Lucht et al., 2006; Scheffer et al., 2012; Lasslop et al., 2016) (see also Section 5.4.3). Such transitions may be related to (i) large-scale changes in mean climate conditions crossing particular climate thresholds (Joos et al., 2001; Cox et al., 2004; Lucht et al., 2006; Hirota et al., 2011; Scheffer et al., 2012; Le Page et al., 2017; Zemp et al., 2017), (ii) temperature and precipitation extremes (Staver et al., 2011; Higgins and Scheiter, 2012; Scheffer et al., 2012; Pavlov, 2015; Zemp et al., 2017), or (iii) possible enhancement and intermittency in fire activity (Staver et al., 2011; Higgins and Scheiter, 2012; Lasslop et al., 2016; Brando et al., 2020). Simulated changes in forest cover are a combination of the effects of CO_2 on photosynthesis and water-use efficiency (Section 5.4.1), and the effects of climate change on photosynthesis, respiration and disturbance (Section 5.4.3). In ESMs, direct CO_2 effects tend to enhance forest growth, but the impacts of climate change vary between being predominantly negative in the tropics and predominantly positive in the boreal zone (Figure 5.27).

Most ESMs project continuing carbon accumulation in tropical forests as a result of direct CO_2 effects overwhelming the negative effects of climate change (Huntingford et al., 2013; Drijfhout et al., 2015;

Boulton et al., 2017). In the real world, forests may be less vulnerable to climate changes than those modelled in ESMs because of the greater plant trait diversity which confers additional resilience (Reyer et al., 2015; Levine et al., 2016; Sakschewski et al., 2016), and also because of possible acclimation of vegetation to warming (Good et al., 2011, 2013; Lloret et al., 2012; Mercado et al., 2018). Contrary, forests may be more vulnerable in the real world due to indirect climate change effects such as insect outbreaks and diseases not considered here (Section 5.4.3.2) or model limitations in representing the effects disturbances such as wildfire and droughts. In general, forests are most vulnerable when climate change is combined with increased rates of direct deforestation (Nobre et al., 2016; Le Page et al., 2017).

In order to estimate an upper limit on the impact of Amazon forest dieback on atmospheric CO_2, we consider the *very unlikely* limiting case of negligible direct-CO_2 effects (Section 5.4.1). Emergent constraint approaches (Section 5.4.6) may be used to estimate an overall loss of tropical land carbon due to climate change alone, of around 50 PgC per ^{o}C of tropical warming (Cox et al., 2013b; Wenzel et al., 2014). This implies an upper limit to the release of tropical land carbon of <200 PgC over the 21st century (assuming tropical warming of <4^{o}C, and no CO_2-fertilisation), which translates to $dCO_2/dt < 0.5$ ppm yr^{-1}.

Boreal forest dieback is not expected to change the atmospheric CO_2 concentration substantially because forest loss at the south is partly compensated by (i) temperate forest invasion into the previous boreal area and (ii) boreal forest gain at the north (Friend et al., 2014; Kicklighter et al., 2014; Schaphoff et al., 2016) (*medium confidence*). An upper estimate of this magnitude, based on statistical modelling of climate change alone, is of 27 Pg vegetation C loss in the southern boreal forest, which is roughly balanced by gains in the northern zone (Koven, 2013). Carbon release from vegetation and soil due to wildfires in boreal regions (Eliseev et al., 2014b; Turetsky et al., 2015; Walker et al., 2019a) is also not expected to change this estimate substantially because of its small present-day value of about 0.2 PgC yr^{-1} (van der Werf et al., 2017), and because of *likely* increases in precipitation in boreal regions (Chapter 4, Section 4.5.1).

5.4.9.1.2 Biogenic Emissions Following Permafrost Thaw

There is large uncertainty in release of GHGs from permafrost in the 21st century with the largest of these estimates implying tens to hundreds of gigatons of carbon released in the form of CO_2 (Box 5.1) and methane emissions up to 100 TgCH$_4$ yr^{-1} (Box 5.1). A carbon dioxide release of such magnitude would lead to an increase in the CO_2 accumulation rate in the atmosphere of ≤1 ppm yr^{-1}. These emissions develop at multi-decadal timescale. Assuming a CH_4 lifetime in the atmosphere of the order of 10 years and the associated feedback parameter of 1.34 ± 0.04 (Chapter 6, Section 6.2.2.1), this would increase the atmospheric methane content by about 500 ppb over the century, corresponding to a rate of ≤10 ppb yr^{1}. Irrespective of its origin, additional methane accumulation of such a magnitude is not expected to modify the temperature response to anthropogenic emissions by more than a few tens of °C cent (Gedney, 2004; Eliseev et al., 2008; Denisov et al., 2013). Emissions from the permafrost are assessed in Box 5.1.

5.4.9.1.3 Methane Release from Clathrates

The total global clathrate reservoir is estimated to contain 1500–2000 PgC (Archer et al., 2009; Ruppel and Kessler, 2017), held predominantly in ocean sediments with only an estimated 20 PgC in and under permafrost (Ruppel, 2015). The present-day methane release from shelf clathrates is <10 TgCH$_4$ yr^{-1} (Kretschmer et al., 2015; Saunois et al., 2020). Despite polar amplification (Chapter 7), substantial releases from the permafrost-embedded subsea clathrates is *very unlikely* (Minshull et al., 2016; Malakhova and Eliseev, 2017, 2020). This is consistent with an overall small release of methane from the shelf clathrates during the last deglacial despite large reorganisations in climate state (Bock et al., 2017; Petrenko et al., 2017; Dyonisius et al., 2020). The long timescales associated with clathrate destabilisation makes it *unlikely* that CH_4 release from the ocean to the atmosphere will deviate markedly from the present-day value through the 21st century (Hunter et al., 2013), corresponding to no more than additional 20 ppb of atmospheric methane (i.e. <0.2 ppb yr^{-1}). Another possible source of CH_4 are gas clathrates in deeper terrestrial permafrost and below it (Buldovicz et al., 2018; Chuvilin et al., 2018), which may have caused recent craters in the north of Russia (Arzhanov et al., 2016, 2020; Arzhanov and Mokhov, 2017; Kizyakov et al., 2017, 2018). Land clathrates are formed at depths >200 m (Ruppel and Kessler, 2017; Malakhova and Eliseev,

ACCEPTED VERSION SUBJECT TO FINAL EDITS

2020), which precludes a substantial response to global warming over the next few centuries and associated emissions.

Thus, it is *very unlikely* that CH_4 emissions from clathrates will substantially warm the climate system over the next few centuries.

5.4.9.2 Abrupt Changes Detected in ESM Projections

Projecting abrupt changes is intrinsically difficult, because by definition abrupt changes occur in a small region of the parameter and/or forcing space. At the time of the AR5 there was no available systematic study of abrupt changes or tipping points in ESMs. An analysis of ESMs since the AR5 has identified a number of abrupt changes in the CMIP5 ensemble (Drijfhout et al., 2015; Bathiany et al., 2020). These include abrupt changes in tropical forests and high-latitude greening, permafrost thaw, and vegetation composition change (Bathiany et al., 2020). Most modelled abrupt changes were detected in boreal and tundra regions, with few models showing Amazon forest dieback (Bathiany et al., 2020).

Based on the evidence presented in this section, we conclude that abrupt changes and tipping points in the biogeochemical cycles lead to additional uncertainty in 21st century GHG concentrations changes, but these are *very likely* to be small compared to the uncertainty associated with future anthropogenic emissions (*high confidence*).

5.4.10 Long Term Response past 2100

AR5 assessed with *very high confidence* that the carbon cycle in the ocean and on land will continue to respond to climate change and rising atmospheric CO_2 concentrations created during the 21st century (WGI, Chapter 6, Executive Summary). Since AR5, experiments with the CESM1 model under the RCP8.5 extension scenario out to 2300, suggest that both land and ocean carbon-climate feedbacks strengthen in time, land and ocean carbon-concentration feedbacks weaken, and the relative importance of ocean sinks versus land sinks increases (Randerson et al., 2015). Under high emissions scenarios, this relative strengthening of land carbon-climate feedbacks leads the terrestrial biosphere to shift from sink to source at some point after 2100 in all of the CMIP5 ESMs and CMIP5-era EMICs (Tokarska et al., 2016). The strengthening of land and ocean carbon-climate feedbacks projected beyond 2100 under high emissions scenarios offsets the declining climate sensitivity to incremental increases of CO_2, leading to a net strengthening of carbon cycle feedbacks, as measured by the gain parameter, from one century to the next (Randerson et al., 2015).

Figure 5.30 shows carbon cycle changes to 2300 under three SSP scenarios with long-term extensions: SSP5–8.5, SSP5–3.4–overshoot, and SSP1–2.6, for four CMIP6 ESMs and one EMIC. Under all three scenarios, all five models project a reversal of the terrestrial carbon cycle from a sink to a source. However, the reasons for these reversals under very high emissions and low/negative emissions are very different. Under the SSP5–8.5 scenario, the terrestrial carbon-climate feedback is projected to strengthen, while the carbon-concentration feedbacks weaken after emissions peak at 2100, which together drives the land to become a net carbon source after 2100 (Tokarska et al., 2016). The difference in both timing and magnitude of this transition across the ensemble, leads to an assessment of *medium confidence* in the likelihood and *low confidence* in the timing and strength, of the land transitioning from a net sink to a net source under such a scenario. Based on *high agreement* across all available models, we assess with *high confidence* that the ocean sink strength would weaken but not reverse under a long-term high-emissions scenario. In the SSP5–3.4–overshoot scenario, both the terrestrial and ocean reservoirs act as transient carbon sources during the overshoot period, when net anthropogenic CO_2 emissions are negative and CO_2 concentrations are falling, and then revert to near-zero (land) or weak sink (ocean) fluxes after stabilisation of atmospheric CO_2. The SSP1–2.6 scenario, characterised by lower peak CO_2 concentrations, a smaller overshoot, and much less carbon loss from land use change, shows instead a relaxation towards a neutral biosphere on land and a sustained weak sink in the ocean (see also Section 5.6.2.2.1.2).

[START FIGURE 5.30 HERE]

Figure 5.30: Trajectories of carbon cycle dynamics for models beyond 2100. Shown are three scenarios, SSP5–8.5, SSP5–3.4–overshoot, and SSP1–2.6, from four ESMs (CanESM5, UKESM1, CESM2-WACCM, IPSL-CM6a-LR) and one EMIC (UVIC-ESCM, (Mengis et al., 2020)) for which extensions beyond 2100 are available. Solid lines represent the median flux value across the ensemble, and shading represents 15th–85th percentiles across the ensemble. Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

5.4.11 Near-Term Prediction of Ocean and Land Carbon Sinks

The IPCC AR5 (WGI, Section 11.3.2) assessed near-term climate predictability based on ESMs initialised from the observed climate state. Since the AR5, a growing number of prediction systems have been developed based on ESMs that include the ocean and land carbon cycle components. Predictability of key physical climate variables (assessed in Chapter 4) provides a platform to establish predictive skill for interannual variations in the strength of the natural carbon sinks in response to internal climate variability. In most systems the carbon cycle components are only indirectly initialised and respond to the initialised climate variations (Li et al., 2019). This subsection synthesises information on predictability of the land and ocean carbon sinks using both the idealised potential predictability and the actual predictability skill measures.

Longer-term memory residing in the ocean enables predictability of the ocean carbon sink (McKinley et al., 2017; Li and Ilyina, 2018). The predictive horizon of the globally integrated air-sea CO_2 fluxes has been assessed in perfect-model frameworks that are based on an idealised ensemble of simulations in which each ensemble member serves as a verification, while no observations are assessed. Perfect-model studies provide an estimate of the upper range of potential predictability for the integrated air-sea CO_2 fluxes of about 2 years globally and up to a decade in some regions (Séférian et al., 2018a; Spring and Ilyina, 2020). Evidence is also emerging for predictive skill of the global air-sea CO_2 fluxes of up to 6 years based-on prediction systems initialised with observed physical climate states (Li et al., 2019), with a potential for even longer-term regional predictability in some regions including the North Atlantic and subpolar Southern Ocean (Li et al., 2016a; Lovenduski et al., 2019b).

Models suggest that predictability of the air-sea CO_2 flux is related to predictability of ocean biogeochemical state variables such as dissolved inorganic carbon (DIC) and total alkalinity (TA) (Lovenduski et al., 2019b), as well as the mixed layer depth (Li et al., 2016a). Temperature variations largely control shorter-term predictability of the ocean carbon sink, while longer term predictability is related to non-thermal drivers such as ocean circulation and biology (Li et al., 2019). Although there is a substantial spatial heterogeneity, initialised predictions suggest stronger multi-year variations of the air-sea CO_2 flux and generally tend to outperform uninitialized simulations on the global scale (Li et al., 2019). The predictive skill of air-sea CO_2 flux shows a consistent spatial pattern in different models despite the wide range of techniques used to assimilate observational information (Regnier et al., 2013a). ESM-based prediction systems also demonstrate predictability of other marine biogeochemical properties such as net primary production (Séférian et al., 2014; Yeager et al., 2018; Park et al., 2019) and seawater pH (Brady et al., 2020).

Seasonal predictability of air-land CO_2 flux up to 6–8 months is driven by the state of ENSO (Zeng et al., 2008; Betts et al., 2018). Fewer land carbon initialised predictions are available from decadal prediction systems, yet they tend to outperform the uninitialized simulations in capturing the major year-to-year variations as indicated by higher correlations with the Global Carbon Budget estimates. There is growing evidence that potential predictive skill of air-land CO_2 flux is maintained out to a lead-time of 2 years (Lovenduski et al., 2019a); this predictability horizon is also supported by perfect model studies (Séférian et al., 2018a; Spring and Ilyina, 2020). The origins of this interannual predictability are not yet fully

ACCEPTED VERSION SUBJECT TO FINAL EDITS

understood. However, they seem to be associated with the oscillatory behaviour of ENSO (Séférian et al., 2014) and the predictability of terrestrial ecosystem drivers such as ecosystem respiration and gross primary production (Lovenduski et al., 2019b). Initialised simulations suggest that observed variability in the land carbon sink is improved through initialisation of prediction systems with the observed state of the physical climate.

The predictability horizon of variations in atmospheric CO_2 growth-rate are not yet fully established in the literature. However, predictive skill of the land and ocean carbon sinks show a potential to establish predictability of variations in atmospheric CO_2 up to 2 years in advance in the initialised prediction systems with an upper bound of up to 3 years in a perfect-model study (Spring and Ilyina, 2020); this skill is primarily limited by the terrestrial carbon sink predictability.

5.5 Remaining Carbon Budgets

Science at the time of the IPCC AR5 established a near-linear relationship between cumulative emissions of CO_2 and the resulting global warming (Allen et al., 2009; Matthews et al., 2009; Meinshausen et al., 2009; Zickfeld et al., 2009; Collins et al., 2013; Stocker et al., 2013;). The amount of global warming per unit of cumulated CO_2 emissions is called the transient climate response to cumulative emissions of carbon dioxide (TCRE). This TCRE relationship is now used to estimate the amount of CO_2 emissions that would be consistent with limiting global warming to specific levels (Allen et al., 2009; Matthews et al., 2009; Meinshausen et al., 2009; Zickfeld et al., 2009; Matthews et al., 2012; Collins et al., 2013; Stocker et al., 2013; Knutti and Rogelj, 2015; Rogelj et al., 2016; Goodwin et al., 2018; Rogelj et al., 2019). The remainder of CO_2 emissions that would be in line with limiting global warming to a specific temperature level (while accounting for all other factors affecting global warming) can be estimated with help of the TCRE and is referred to as the remaining carbon budget (Rogelj et al., 2019; Matthews et al., 2020). Section 5.5.1 first assesses the TCRE as one of the core concepts underlying the notion of a remaining carbon budget and Section 5.5.2 then integrates this with the assessment of other contributing factors from across this assessment to provide a consolidated assessment following the approach of the IPCC SR1.5 (Rogelj et al., 2018b). The historical carbon budget of CO_2 already emitted is assessed in Section 5.2.1.5.

5.5.1 Transient Climate Response to Cumulative Emissions of carbon dioxide (TCRE)

5.5.1.1 Contributing Physical Processes and Theoretical Frameworks

The processes that translate emissions of CO_2 into a change in global temperature (terrestrial and oceanic carbon uptake, radiative forcing from CO_2, and ocean heat uptake) are governed by complex mechanisms that all evolve in time (Gregory et al., 2009) (Sections 3.5, 4.3, 4.5, 5.4, and 7.3, Cross-Chapter Box 5.3). Starting with an initial description in AR5 (Collins et al., 2013a; Stocker et al., 2013c) a body of literature has since expanded the understanding of physical mechanisms from which a simple proportional relationship between cumulative emissions of CO_2 and change in global temperature (expressed in either global mean surface temperature, GMST or global mean surface air temperature, GSAT) arises.

Studies have focused on two key features of the TCRE relationship: (i) why the relationship is nearly constant in time (Goodwin et al., 2015; MacDougall and Friedlingstein, 2015; Williams et al., 2016; Ehlert et al., 2017; Katavouta et al., 2018); and (ii) why and under which conditions the relationship is independent on the historical rate (or pathway) of CO_2 emissions (MacDougall, 2017; Seshadri, 2017).

There is increased confidence in the near-constancy of TCRE because of the variety of methods that have been used to examine this relationship: sensitivity studies with Earth system models of EMICs (Herrington and Zickfeld, 2014; Ehlert et al., 2017); theory-based equations used to examine Earth system model (ESM) and EMIC output (Goodwin et al., 2015; Williams et al., 2016, 2017c); and simple analytical models that capture aspects of the TCRE relationship (MacDougall and Friedlingstein, 2015). All studies agree that the near-constancy of the TCRE arises from compensation between the diminishing sensitivity of radiative

ACCEPTED VERSION SUBJECT TO FINAL EDITS

forcing to CO_2 at higher atmospheric concentration, and the diminishing ability of the ocean to take up heat and carbon at higher cumulative emissions (Allen et al., 2009; Matthews et al., 2009; Frölicher and Paynter, 2015; Goodwin et al., 2015; Gregory et al., 2015; MacDougall and Friedlingstein, 2015; MacDougall, 2016; Tokarska et al., 2016; Ehlert et al., 2017).

The question whether and under which conditions the TCRE relationship is independent of the historical rate of CO_2 emissions (also referred to as 'pathway independence of TCRE') has been examined by using simple mathematically-tractable models (MacDougall, 2017; Seshadri, 2017). Based on the assumption that the cumulative fraction of carbon taken up by the terrestrial biosphere is constant, and that the climate feedback parameter and ocean heat uptake efficacy do not change in time, both studies agree that pathway independence is sensitive to the rate of CO_2 emissions, such that pathway independence is expected to breakdown at both very high and very low absolute CO_2 emission rates (MacDougall, 2017; Seshadri, 2017). Note that in pathways with strongly declining emissions, the cumulative sink fraction by the combined terrestrial biosphere and ocean is expected to increase (see Figure 5.25 in Section 5.4.5). The studies also agree that no similar relationship analogous to TCRE can be expected for short-lived non-CO_2 forcers, for which the annual emissions are a closer proxy for the implied warming (Collins et al., 2013a); Sections 6.4, 7.6. MacDougall, (2017) suggests that two additional constraints are required to create pathway independence: first, the transport of heat and carbon into the deep ocean should be governed by processes with similar timescales; and second, the ratio of the net change in the atmospheric carbon pool to the net change in the ocean carbon pool should be close to the ratio of the enhanced longwave radiation to space (i.e. the radiative response of the surface) to ocean heat uptake. If these ratios are identical then TCRE would be completely path independent (MacDougall, 2017). If the ratios are close but not identical, TCRE would be only approximately path independent over a wide range of cumulative emissions (MacDougall, 2017) (Cross-Chapter Box 5.3).

The land carbon cycle does not appear to play a fundamental role in the origin of the linearity and path-independence of TCRE (Goodwin et al., 2015; MacDougall and Friedlingstein, 2015; Ehlert et al., 2017), but, in contrast to the ocean sink, dominates the uncertainty in the magnitude of TCRE by modulating the cumulative airborne fraction of carbon (Goodwin et al., 2015; Williams et al., 2016; Katavouta et al., 2018; Jones and Friedlingstein, 2020). Some terrestrial carbon cycle feedbacks (such as the permafrost carbon feedback, Section 5.4.8, Box 5.1) have the potential to alter both the linearity and pathway independence of TCRE, if such feedbacks significantly contribute carbon to the atmosphere (MacDougall and Friedlingstein, 2015) (Section 5.5.1.2.3, Section 5.4.8, Box 5.1). A recent study also shows how the value of TCRE can depend on the effect of ocean ventilation modulating ocean heat uptake (Katavouta et al., 2019).

Cross-Chapter Box 5.3: The Ocean Carbon-Heat Nexus and Climate Change Commitment

Contributors: Pedro M.S. Monteiro (South Africa), Jean-Baptiste Sallée (France), Piers Foster (UK), Baylor Fox-Kemper (USA), Helen Hewitt (UK), Masao Ishii (Japan), Joeri Rogelj (Belgium), Kirsten Zickfeld (Canada/Germany)

Context

In the past 60 years the ocean has taken up and stored 23 ± 5% of anthropogenic carbon emissions (*medium confidence*; Section 5.2.1.3) as well as more than 90% of the heat that has accumulated in the Earth system (referred to as excess heat) since the 1970s (Sections 7.2.2, 9.2.2, 9.2.3; Box 7.2;) (Frölicher et al., 2015; Talley et al., 2016; Gruber et al., 2019a; Hauck et al., 2020). The interplay between heat and CO_2 uptake by the ocean has not only played a major role in slowing the rate of global warming but provides a first order influence in determining the unique properties of a metric of the coupled climate-carbon cycle response, transient climate response to cumulative carbon emissions (TCRE), which is critical to setting the future remaining carbon emissions budget (Sections 5.5.1.3, 5.5.4). This role of the ocean in the uptake of heat and anthropogenic CO_2 and related feedbacks is what we term here the "Ocean Heat-Carbon Nexus". The ocean

ACCEPTED VERSION SUBJECT TO FINAL EDITS

processes behind this nexus are important in shaping and understanding the near-linear relationship between cumulative CO_2 emissions and global warming (TCRE) as well as the uncertainties in future projections of TCRE properties (Zickfeld et al., 2016; Bronselaer and Zanna, 2020; Jones and Friedlingstein, 2020), its path independence (MacDougall, 2017), and the warming commitment after cessation of greenhouse gas emissions (ZEC) (Zickfeld et al., 2016; Ehlert and Zickfeld, 2017; Section 5.5.2). In this box, we assess the role of the ocean and its physical and chemical thermodynamic processes that shape these striking characteristics.

The role of the ocean in setting the coupled climate-carbon cycle response is threefold: firstly, the ocean and land carbon sinks together set the airborne fraction (AF) of CO_2 in the atmosphere, which sets the radiative forcing that drives the additional heat in the atmosphere most of which is taken up by the ocean (Katavouta et al., 2019; Williams et al., 2019; Sections 7.2, 9.2). However, the land carbon sink does not appear to play an important role in determining the linearity and path-independence of TCRE (Section 5.5.1.1; Goodwin et al., 2015; MacDougall and Friedlingstein, 2015; Ehlert et al., 2017). Secondly, the ocean sets the thermal response through ocean heat uptake (Section 9.2; Frölicher et al., 2015; Bronselaer and Zanna, 2020). Thirdly, there is a feedback within the ocean heat-carbon nexus as ocean warming, particularly under low or no mitigation scenarios weakens the ocean sink of CO2, which influences the AF, and hence the radiative forcing (Williams et al., 2019) (Box 7.1). The near-linear relationship between cumulative CO_2 emissions and global warming (TCRE) is thought to arise to a large extent from the compensation between the decreasing ability of the ocean to take up heat and CO_2 at higher cumulative CO_2 emissions, pointing to similar processes that determine ocean uptake of heat and carbon (Goodwin et al., 2015; MacDougall and Friedlingstein, 2015; Williams et al., 2016; Zickfeld et al., 2016; Ehlert et al., 2017; Section 5.5.1.1).

Processes the drive the Ocean Carbon - Heat Nexus and its change

The air-sea flux of heat and all gases across the ocean interface is driven by a common set of complex and difficult to observe turbulent diffusion and mixing processes (Wanninkhof et al., 2009; Wanninkhof, 2014; Cronin et al., 2019; Watson et al., 2020; Sections 5.2.1.3; 9.2.1.2). These processes are typically simplified into widely verified expressions that link the flux to wind stress, the solubility and the gradient across the air-sea interface (*medium confidence*). Because the ocean has a higher heat capacity than the atmosphere (heat capacity of the upper 100 m of the ocean is about 30 times larger than the heat capacity of the atmosphere), the partitioning of heat between the atmosphere and the ocean is primarily influenced by the temperature differences between air and seawater. Similarly, the unique seawater carbonate buffering capacity, enables CO_2 to be stored in the ocean as dissolved salts, rather than just as dissolved gas, which increases the capacity of seawater to store CO_2 by two orders of magnitude beyond the solubility of CO_2 gas and approximate the partitioning ratio of heat between the atmosphere and the ocean (Zeebe and Wolf-Gladrow, 2009; Bronselaer and Zanna, 2020; Section 9.2.2.1). The role of the biological carbon pump in influencing the ocean sink of anthropogenic carbon into the ocean interior is assessed to be minimal during the historical period but this may change, particularly in regional contexts, by 2100 (*medium confidence*) (Laufkötter et al., 2015; Kwiatkowski et al., 2020). Its role is important in the natural or pre-industrial carbon cycle (*medium confidence*) (Henson et al., 2016).

Under climate change, the buffering capacity of the ocean decreases (increasing Revelle Factor), which reflects a decreasing capacity for the ocean to take up additional anthropogenic CO_2 and store it in the DIC reservoir (Egleston et al., 2010). In contrast to CO_2, there is no physical limitation that would reduce the ability of surface ocean temperature to equilibrate with the atmospheric temperature. However, both carbon and heat fluxes depend on air-sea heat fluxes that depend on gradients of characteristics at the air-sea interface. These gradients at the air-sea interface respond to ocean dynamics, such as the volume of the surface mixed-layer that equilibrates with the atmosphere, and ocean circulation that can flush the surface layer with water-masses that have not equilibrated with the atmosphere for a long time. Limited recent evidence has suggested that the effect of small-scale dynamics absent in climate and earth system models might be locally important in this regard (Bachman and Klocker, 2020). In summary, changes in heat and carbon uptake by the ocean rely on a combination of unique chemical and shared physical processes any of which have the potential to disrupt the coherence of heat and CO_2 change in the ocean.

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Spatial pattern of air-sea fluxes and storage

Large scale regional and global ocean circulation shape the spatial pattern of the uptake and storage of both CO_2 and heat (see Figure 5.8 for carbon; Figure 9.6 for heat observations; Section 9.2; (Frölicher et al., 2015; Bronselaer and Zanna, 2020). This coherence of spatial patterns driven by the large-scale ocean circulation has three aspects: firstly, notwithstanding interannual - decadal variability in heat and CO_2 uptake, there is a spatial coherence of the temporally integrated uptake at the air-sea boundary, particularly in the Southern Ocean (Cross-Chapter Box 5.3, Figure 1; Talley et al., 2016; Keppler and Landschützer, 2019; Auger et al., 2021). Secondly, the importance of the meridional overturning circulation in the subsequent storage of both heat and CO_2 in mode, intermediate and deep waters of the ocean interior (Section 9.2). Of particular note are the roles of the North Atlantic Ocean (Section 9.2.3.1) and the Southern Ocean (Section 9.2.3.2) in linking the spatial pattern of air-sea fluxes, the storage of heat and carbon, and ultimately in understanding and predicting the sensitivity of the carbon – heat nexus to climate change (Frölicher et al., 2015; Thomas et al., 2018; Wu et al., 2019).

[START CROSS-CHAPTER BOX 5.3, FIGURE 1 HERE]

Cross-Chapter Box 5.3, Figure 1: CMIP6 multi-model mean of changes in zonally integrated (a) carbon and (b) heat storage in ocean between the pre-industrial and the modern period. Carbon corresponds to dissolved inorganic carbon. Data are shown for the upper 2000m. The modern period is 1995–2014. Adapted from (Frölicher et al., 2015))

[END CROSS-CHAPTER BOX 5.3, FIGURE 1 HERE]

The role of the large-scale circulation in shaping these fluxes is to (i) flush the ocean surface layer with deep waters that are relatively cold and with weak or no anthropogenic CO_2 and heat content because they have been isolated from the atmosphere for centuries, and (ii) transport the anthropogenic CO_2 and heat at depth, away from the atmosphere (Frölicher et al., 2015; Marshall et al., 2015; Armour et al., 2016). For instance, in the Southern Ocean upwelled water-masses uptake large amount of anthropogenic CO_2 and heat (Cross-Chapter Box 5.3, Figure 1), which are then exported northward by the circulation to be stored at depth in the Southern Hemisphere subtropical gyres (Cross-Chapter Box 5.3, Figure 1; Figure 9.7). In the North Atlantic, the signature of the Atlantic meridional overturning circulation (AMOC) is also clearly visible, with large amounts of heat and carbon being stored beneath the North Atlantic subtropical gyre at 1 km depth (Cross-Chapter Box 5.3, Figure 1). In summary, the net air-sea fluxes of anthropogenic CO_2 and heat depend on large-scale circulation, which is associated with upper ocean stratification, mixed-layer depth, and water-mass formation, transport and mixing (Sections 9.1; 9.2; 9.3).

Changes in ocean processes and impact on the ocean carbon-heat nexus

Future projections of the ocean carbon-heat nexus in the second half of the 21st century, particularly those under weak or no mitigation scenarios, are characterized by the strengthening of the two largest positive feedbacks: weakening surface ocean CO_2 buffering capacity (increasing Revelle Factor) and warming that further reduces CO_2 solubility and strengthens ocean stratification, which reduces exchange between the ocean surface and interior (Jiang et al., 2019; Bronselaer and Zanna, 2020). These are offset by a growing but scenario-dependent negative feedback from increasing carbon and heat air sea fluxes towards the ocean, due to increased atmospheric temperature and CO_2 concentrations (Talley et al., 2016; Jiang et al., 2019; McKinley et al., 2020). The Southern Ocean (SO) in particular is one of the regions where the projected feedback can be largest and where inter-model differences are strongest (Roy et al., 2011; Frölicher et al., 2015; Hewitt et al., 2016; Mongwe et al., 2018). These projected trends in ocean carbonate chemistry (5.4.2), together with surface ocean warming (Section 9.2.1.1), explain the slow down and long-term reduction of the ocean sink for anthropogenic CO_2 even as emissions continue to rise beyond 2050 under weak to no mitigation scenarios (Section 5.4: Figure 5.25; Technical Summary TS Box 7 and Figure 2.7.1). Projected change in the North Atlantic and Southern Ocean overturning circulation also impact air-sea fluxes of heat

ACCEPTED VERSION SUBJECT TO FINAL EDITS

and carbon. The *very likely* decline in AMOC in the 21st century for all shared socioeconomic pathways (SSP) scenarios (Section 9.2.3.1) tends to reduce heat and carbon uptake translating in a positive feedback. In contrast, in the Southern Ocean, the future 21st century projected increase in upper ocean overturning circulation (*low confidence*) due to increasing wind forcing projected for all scenarios, except those with large mitigation (SSP1–2.6), translate in a negative feedback with increasing heat and carbon uptake and storage despite the increasing stratification and outgassing of natural CO_2 in the upwelling zone (Sections 9.2.3.2; 5.2.1.3).

In summary, a combination of unique chemical properties of seawater carbonate combined with shared physical ocean processes explain the coherence and scaling in the uptake and storage of both CO_2 and heat in the ocean, which is the basis for the carbon-heat nexus (*high confidence*). In this way the processes of the ocean carbon – heat nexus help understand the quasi-linear and path independence of properties of TCRE, which forms the basis for the ZEC (Section 5.5) (*medium confidence*). Future projections under low or no mitigation indicate with *high confidence* that carbon chemistry and warming will strengthen the positive feedback to climate change by reducing ocean carbon uptake, and *medium confidence* that ocean circulation may partially compensate that positive feedback by slightly increasing anthropogenic carbon storage. Increasing ocean warming and stratification may decrease exchanges between the surface and subsurface ocean, which could reduce the path independence of TCRE, though this effect can be partially counterbalanced regionally by increasing circulation associated with increasing winds (*low confidence*).

[END CROSS-CHAPTER BOX 5.3]

5.5.1.2 Assessment of Limits of the TCRE Concept

5.5.1.2.1 Sensitivity to amount of cumulative CO_2 emissions

AR5 indicated that the concept of a constant ratio of cumulative emissions of CO_2 to temperature was applicable to scenarios with increasing cumulative CO_2 emissions up to 2000 PgC (Collins et al., 2013a). Recent analyses have added confidence to this insight (Herrington and Zickfeld, 2014; Steinacher and Joos, 2016) and have also shown some evidence of a potentially larger window of constant TCRE (Leduc et al., 2015; Tokarska et al., 2016). Using an analytical approach, MacDougall and Friedlingstein (2015) quantified a window of constant TCRE – defined as the range in cumulative emissions over which the TCRE remains within 95% of its maximum value – as between 360 to 1560 PgC. However, models with a more sophisticated ocean representation suggest that TCRE could also remain constant for considerably larger quantities of cumulative emissions, up to at least 3000 PgC (Leduc et al., 2015; Tokarska et al., 2016). Beyond this upper limit, studies are inconclusive with some suggesting that TCRE will decrease (Leduc et al., 2015) and others indicating that the linearity would hold up to as much as 5000 PgC (Tokarska et al., 2016).

As cumulative emissions increase, weakening land and ocean carbon sinks increase the airborne fraction of CO_2 emissions (see Section 5.4.5, Figure 5.25), but each unit increase in atmospheric CO_2 has a smaller effect on global temperature owing to the logarithmic relationship between CO_2 and its radiative forcing (Matthews et al., 2009; Etminan et al., 2016). At high values of cumulative emissions, some models simulate less warming per unit CO_2 emitted, suggesting that the saturation of CO_2 radiative forcing becomes more important than the effect of weakened carbon sinks (Herrington and Zickfeld, 2014; Leduc et al., 2015). The behaviour of carbon sinks at high emissions levels remains uncertain, as models used to assess the limits of the TCRE show a large spread in net land carbon balance (Section 5.4.5) and most estimates did not include the effect of permafrost carbon feedbacks (Sections 5.5.1.2.3, 5.4). The latter would tend to further increase the airborne fraction at high cumulative emissions levels, and could therefore extend the window of linearity to higher total amounts of emissions (MacDougall et al., 2015). Leduc et al. (2016) suggested further that a declining strength of snow and sea-ice feedbacks in a warmer world would also contribute to a smaller TCRE at high amounts of cumulative emissions. On the other hand, Tokarska et al. (2016) suggested that a large decrease in TCRE for high cumulative emissions is only associated with some EMICs; in the four ESMs analysed in their study, the TCRE remained approximately constant up to 5000 PgC, owing to stronger declines in the efficiency of ocean heat uptake in ESMs compared to EMICs.

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Overall, there is *high agreement* between multiple lines of evidence (*robust evidence*) resulting in *high confidence* that TCRE remains constant for the domain of increasing cumulative CO_2 emissions until at least 1500 PgC, with *medium confidence* of it remaining constant up to 3000 PgC because of less agreement across available lines of evidence.

5.5.1.2.2 Sensitivity to the Rate of CO_2 Emissions

Global average temperature increase responds over a timescale of about 10 years following the emission of a 100 PgC pulse of CO_2 (Joos et al., 2013; Ricke and Caldeira, 2014), with larger emission pulses associated with longer timescales and smaller pulses with shorter ones (Joos et al., 2013; Matthews and Solomon, 2013; Zickfeld and Herrington, 2015). This behaviour is confirmed in other studies, including those that calculate the temperature response to an instantaneous doubling or quadrupling of atmospheric CO_2 (Matthews et al., 2009; Gillett et al., 2013; Herrington and Zickfeld, 2014; Leduc et al., 2015; Hajima et al., 2020b). These findings suggest that the TCRE is sensitive to the rate of emissions, but studies assessing this sensitivity have found diverging results. For example, an increase in TCRE and its surrounding uncertainty was reported for experiments that imply a gradual decline in annual CO_2 emissions (Tachiiri et al., 2019). These studies suggest that in most cases TCRE would be expected to increase in scenarios with decreasing annual emissions rates. This increase in TCRE for annual CO_2 emissions declining towards zero can be the result of the zero emissions commitment (ZEC) which is the amount of warming projected to occur following a complete cessation of emissions (see Chapter 4, Section 4.7.2 for its assessment), as well as Earth system processes that are unrepresented in current TCRE estimates (Section 5.5.2.2.4) and other factors. When using TCRE to estimate CO_2 emissions consistent with a specific maximum warming level these factors have to be taken into account (see Figure 5.31). Combined with recent literature on the ZEC (MacDougall et al., 2020) and emissions pathways (Huppmann et al., 2018) and noting the lack of literature that disentangles these various contributions, there is *medium evidence* and *high agreement* resulting in *medium confidence* that TCRE remains a good predictor of CO_2-induced warming when applied in the context of emission reduction pathways, provided that ZEC and long-term Earth system feedbacks are adequately accounted for when emissions decline towards zero (see also next section).

5.5.1.2.3 Reversibility and Earth System Feedbacks

There are relatively few studies that have assessed how the TCRE is expected to change in scenarios of declining emissions followed by net negative annual CO_2 emissions. Conceptually, the literature suggests that the small lag of about a decade between CO_2 emissions and temperature change (Ricke and Caldeira, 2014; Zickfeld and Herrington, 2015) would result in more warming at a given amount of cumulative emissions in a scenario where that emission level is first exceeded and then returned to by deploying negative emissions (referred to as an "overshoot", as is often the case in scenarios that aim to limit radiative forcing in 2100 to 2.6 or 1.9 W/m^2 (Riahi et al., 2017; Rogelj et al., 2018a). Zickfeld et al. (2016) showed this to hold across a range of scenarios with positive emissions followed by negative emissions, whereby the TCRE increased by about 10% across the transition from positive to negative emissions as a result of the thermal and carbon inertia of the deep ocean. However, CMIP6 results for the SSP5–3.4-overshoot scenario show diverging trends across various ESMs (see Section 5.4.10, Figure 5.30). In an idealised CO_2-concentration-driven setting Tachiiri et al. (2019) also reported an increase in TCRE. Exploring pathways with emissions rates and overshoots closer to mitigation pathways considered over the 21st century (in this case up to about 300 PgC), a recent emission-driven EMIC experiment showed pathway independence of TCRE (Tokarska et al., 2019b). Furthermore, also in absence of net negative emissions, warming would not necessarily remain perfectly constant on timescales of centuries and millennia, but could both decrease or increase (Frölicher and Paynter, 2015; Williams et al., 2017b; Hajima et al., 2020b). These additional changes in global mean temperature increase at various timescales are known as the ZEC (Jones et al., 2019; MacDougall et al., 2020), assessed in Section 4.7.2, and have to be integrated when using TCRE to estimate warming or remaining carbon budgets in overshoot scenarios.

The AR5-assessed (Collins et al., 2013b) TCRE range was based in part on the ESMs available at the time, which did not include some potentially important Earth system feedbacks. Since then, a number of studies

ACCEPTED VERSION SUBJECT TO FINAL EDITS

have assessed the importance of permafrost carbon feedbacks in particular on remaining carbon budgets (MacDougall et al., 2015; MacDougall and Friedlingstein, 2015; Burke et al., 2017; Gasser et al., 2018; Lowe and Bernie, 2018), a development highlighted and assessed in the IPCC Special Report on Global Warming of 1.5°C (Rogelj et al., 2018b). MacDougall and Friedlingstein (2015) reported a TCRE increase of about 15% when including permafrost carbon feedbacks. The overall linearity of the TCRE during the 21st century was not affected, but they also found that permafrost carbon feedbacks caused an increase in TCRE on multi-century timescales under declining CO_2 emission rates. In addition, other processes that are not or only partially considered in individual or all ESMs could cause a further increase or decrease of TCRE (Matthews et al., 2020). These are discussed in detail in Section 5.4, but their quantitative effects on TCRE have not yet been explored by the literature.

Whether TCRE remains an accurate predictor of CO_2-induced warming when annual CO_2 emissions reach zero and are followed by net carbon-dioxide removal (also referred to as TCRE reversibility) therefore hinges on contributions of slow components of the climate system that cause unrealised warming from past CO_2 emissions. Such slow components can arise from either physical climate (i.e., ocean heat uptake) or carbon cycle (i.e., ocean carbon uptake and permafrost carbon release) processes. The combined effect of these processes determines the magnitude and sign of the ZEC (MacDougall et al., 2020), which in turn impacts TCRE reversibility. As discussed in Section 4.7.2, recent model estimates of the ZEC suggest a range of ±0.19°C centred on zero (MacDougall et al., 2020). This suggests *limited agreement* among models as to the reversibility of the TCRE in response to net-negative CO_2 emissions. Furthermore, most models used for ZEC assessments to date do not represent permafrost carbon processes, although understanding their contribution is essential to isolate the TCRE contribution. There is therefore *limited evidence* that quantifies the impact of permafrost carbon feedbacks on the reversibility of TCRE, leading to *low confidence* that the TCRE remains an accurate predictor of temperature changes in scenarios of net-negative CO_2 emissions on timescales of more than a half a century.

5.5.1.3 Estimates of TCRE

IPCC AR5 (Collins et al., 2013a) assessed TCRE *likely* to fall in the range of 0.8–2.5°C per 1000 PgC (or per exagrams of carbon, EgC^{-1}) for cumulative emissions up to 2000 PgC, based on multiple lines of evidence. These include estimates based on Earth system models of varying complexity (Matthews et al., 2009; Gillett et al., 2013; Zickfeld et al., 2013), simple climate modelling approaches (Allen et al., 2009; Rogelj et al., 2012) or observational constraints and attributable warming (Gillett et al., 2013).

Since IPCC AR5, new studies have further expanded the evidence base for estimating the value of TCRE. These studies rely on ESMs or EMICs, observational constraints and concepts of attributable warming, or theoretically derived equations (see Table 5.7 for an overview). Several studies have endeavoured to partition the uncertainty in the value of TCRE into constituent sources. For example, TCRE can be decomposed into terms of TCR and the airborne fraction of anthropogenic CO_2 emissions over time (Allen et al., 2009; Matthews et al., 2009). These two terms are assessed individually (see Section 5.4 and Chapter 7, respectively) and allow the integration of evidence assessed elsewhere in the report into the assessment of TCRE (Section 5.5.1.4). Further studies use a variety of methods including analysing CMIP5 (Williams et al., 2017c) or CMIP6 (Arora et al., 2020; Jones and Friedlingstein, 2020) output, conducting perturbed parameter experiments with a single model (MacDougall et al., 2017), Monte-Carlo methods applied to a simple climate model (Spafford and Macdougall, 2020), or observations and estimates of the contribution of CO_2 and non-CO_2 forcers (Matthews et al., 2021). All of the studies agree that uncertainty in climate sensitivity (either Equilibrium Climate Sensitivity (ECS) or Transient Climate Response (TCR)) is amongst the most important contribution to uncertainty in TCRE, with uncertainty in the strength of the land carbon feedback and ocean heat uptake or ventilation having also been identified as crucial to uncertainty in TCRE (Matthews et al., 2009; Gillett et al., 2013; Ehlert et al., 2017; MacDougall et al., 2017; Williams et al., 2017b, 2020; Katavouta et al., 2019; Arora et al., 2020; Jones and Friedlingstein, 2020; Spafford and Macdougall, 2020). Finally, internal variability has been shown to affect the maximum accuracy of TCRE estimates by ±0.1°C per 1000 PgC (5–95% range) (Tokarska et al., 2020).

[START TABLE 5.7 HERE]

Table 5.7: Overview of estimates of studies estimating the transient response to cumulative emissions (TCRE) of CO_2. GSAT = Global mean surface air temperature increase, SAT = surface air temperature (e.g. over land only), SST = sea surface temperature, ECS = equilibrium climate sensitivity. Studies that do not isolate the CO_2-induced warming contribution in their TCRE estimates are not included.

Study	TCRE Range (°C per 1000 PgC)	Notes
Studies available at the time of IPCC AR5		
(Matthews et al., 2009)	1–2.1	5 to 95% range; GSAT; C^4MIP model range
(Allen et al., 2009)	1.4–2.5	5 to 95% range; blended global mean SAT and SSTs (no infilling of coverage gaps); simple model
(Zickfeld et al., 2009)	1.5	Best estimate; GSAT, EMIC
(Williams et al., 2012)	0.8–1.9	Range consistent with 2 to 4.5 °C ECS; GSAT
(Rogelj et al., 2012)	About 1–2	5 to 95% range; historical constraint on GMST increase, but other constraints on GSAT increase MAGICC model calibrated to C^4MIP model range and 2–4.5°C *likely* ECS
(Zickfeld et al., 2013)	1.4–2.5; mean: 1.9	Model range; GSAT, EMICs
(Eby et al., 2013)	1.1–2.1; mean: 1.6	Model range; GSAT, EMICs
(Gillett et al., 2013)	0.8–2.4	Model range; GSAT, CMIP5 ESMs
(Gillett et al., 2013)	0.7–2.0	5 to 95% range; blended global mean SAT and SSTs; observationally constrained estimates of historical warming and emissions
IPCC AR5 (Collins et al., 2013a)	0.8–2.5	Assessed *likely* range; multiple lines of evidence; mixed definition of global average temperature increase
Studies published since IPCC AR5		
(Tachiiri et al., 2015)	0.3–2.4	5 to 95% range; blended global mean SAT and SSTs; JUMP-LCM model perturbed physics ensemble (EMIC)
(Tachiiri et al., 2015)	1.1–1.7	5 to 95% range; blended global mean SAT and SSTs; observationally constrained JUMP-LCM perturbed physics ensemble
(Goodwin et al., 2015)	1.1 ± 0.5	5 to 95% range; theoretically derived TCRE equation constrained by surface warming, radiative forcing, and historic ocean and land carbon uptake from IPCC AR5
(Millar et al., 2017b)	1.0–2.5	5 to 95% range; blended global mean SAT and SSTs (HadCRUT4); observationally constrained probabilistic setup of simple climate model
(Steinacher and Joos, 2016)	1.0–2.7; median: 1.7	5 to 95% range; GSAT, observationally constrained BERN3D-LPJ EMIC
(MacDougall et al., 2017)	0.9–2.5; mean: 1.7	5 to 95% range; GSAT, emulation of 23 CMIP5 ESMs
(Ehlert et al., 2017)	1.2–2.1	Model range; GSAT, UVIC EMIC with varying ocean mixing parameters
(Williams et al., 2017c)	1.4–2.1; mean: 1.8	1-sigma range; GSAT, diagnosed from 10 CMIP5 ESMs
(Millar and Friedlingstein, 2018)	0.9–2.6; best estimate: 1.3	5 to 95% range; blended global mean SAT and SSTs (Cowtan and Way, 2014); detection attribution with observational constraints
(Millar and Friedlingstein, 2018)	best estimate: 1.5	Blended global mean SAT and SSTs (Berkeley Earth); detection attribution with observational constraints
(Millar and Friedlingstein, 2018)	best estimate: 1.2	Blended global mean SAT and SSTs (Cowtan and Way, 2014); detection attribution with observational constraints, with updated historical CO_2 emissions (Le Quéré et al., 2018b)
(Smith et al., 2018a)	1.0–2.2	5 to 95% range; blended global mean SAT and SSTs (Cowtan and Way, 2014); observationally constrained probabilistic setup of simple climate model
(Matthews et al., 2021)	1.0–2.2; median: 1.5	5 to 95% range; blended global mean SAT and SSTs; human-induced warming (Haustein et al., 2017) based on an average of three full coverage datasets; observationally constrained estimate using the current non-CO_2 fraction of total anthropogenic forcing
(Arora et al., 2020)	1.3–2.4; mean: 1.8; median: 1.65	Model range; GSAT, diagnosed CO_2 emissions in CMIP6 ESMs
(Williams et al., 2020)	1.2–2.1; mean: 1.6	1-sigma range; GSAT, diagnosed CO_2 emissions in 9 CMIP6 ESMs
(Jones and Friedlingstein, 2020)	1.2–2.7; median: 1.8	5 to 95% range; GSAT; Estimate based on decomposition presented in (Jones and Friedlingstein, 2020) with ranges of carbon cycle feedback parameters from CMIP6 (Arora et al., 2020), see Section 5.4.
(Spafford and Macdougall, 2020)	1.1–2.9; mean: 1.9; median: 1.8	5 to 95% range; ratio of land SAT and SST; probabilistic assessment of with a zero-dimensional ocean diffusive model
Cross-AR6 lines of evidence		
Transient Climate Response (TCR) and Airborne	1.0–2.3; median: 1.6	5 to 95% range; GSAT; TCR–AF decomposition-based estimate using the assessed range of TCR (Section 7.5, 1.8°C median with 0.4°C 1-sigma

5.5.1.4 Combined assessment of TCRE

Studies differ in how they define TCRE, in the methods they use, and their assumptions, such as the assumed climate sensitivity distribution or the choice of metrics of global temperature change (e.g. GMST or GSAT, see Table 5.7). This makes TCRE estimates from individual studies difficult to compare. The combined assessment of TCRE therefore takes advantage of the well-established decomposition of TCRE in two factors: the transient climate response (TCR) and the airborne fraction (Section 5.5.1.3). This provides a TCRE assessment range for CO_2-induced warming at the time of doubling CO_2 concentrations that builds on the broader Working Group 1 assessment. Expert judgment based on the airborne fraction range found in CMIP6 models (Arora et al., 2020; Jones and Friedlingstein, 2020) suggest a value of 53% with a 1-sigma range of ±6%, which is double the sigma range based on the spread of CMIP6 models only. Combining this range with the AR6 TCR assessment (Section 7.5, best estimate 1.8°C, 1.4–2.2°C *likely* and 1.2–2.4°C *very likely* range) results in a 5–95% range of 1.0–2.3°C per 1000 PgC. Based on expert judgment that accounts for the incomplete coverage of all Earth system components, this result in a consolidated assessment that TCRE would fall *likely* in the range of 1.0–2.3°C per 1000 PgC, with a best estimate of 1.65°C per 1000 PgC. Warming here reflects the human-induced GSAT increase and assumes a normal distribution. Some studies using observational constraints support a lognormal shape for the TCRE distribution (Spafford and Macdougall, 2020), but such a distribution is currently not supported by the combined assessment of TCR and airborne fraction. Finally, this assessed TCRE range needs to be considered in combination with the ZEC (Section 4.7.2) when estimating the CO_2-induced warming of low-emissions scenarios.

5.5.2 Remaining Carbon Budget Assessment

Estimates of remaining carbon budgets consistent with holding global warming below a specific temperature threshold depend on a range of factors which are increasingly being studied and quantified. These factors include (i) well-understood methodological and definitional choices (Friedlingstein et al., 2014a; Rogelj et al., 2016, 2018b) (see Sections 5.5.2.1 and Section 5.5.2.2), and (ii) a set of contributing factors such as historical warming, the TCRE and its limitations, the ZEC (the amount of warming projected to occur following a complete cessation of emissions, see Section 4.7.2), as well as contributions of non-CO_2 climate forcers (Section 5.5.2.2) (Rogelj et al., 2015a, 2015b; MacDougall and Friedlingstein, 2015; Simmons and Matthews, 2016; MacDougall, 2016; Ehlert et al., 2017; Matthews et al., 2017, 2021; Millar et al., 2017a; Tokarska et al., 2018; Goodwin et al., 2018; Mengis et al., 2018; Pfleiderer et al., 2018; Cain et al., 2019). These contributing factors are integrated in an overarching assessment of remaining carbon budgets for limiting global average warming to levels ranging from 1.5°C to 2.5°C relative to pre-industrial levels provided in Section 5.5.2.3. Box 5.2 provides an overview of the methodological advances since AR5 (Collins et al., 2013b).

5.5.2.1 Framework and Earlier Approaches

The IPCC AR6 Glossary (Annex VII) defines remaining carbon budgets as the maximum amount of cumulative net global anthropogenic CO_2 emissions expressed from a recent specified date that would result in limiting global warming to a given level with a given probability, taking into account the effect of other anthropogenic climate forcers, consistent with their assessment in the IPCC SR1.5 (Rogelj et al., 2018b). Studies, however, apply a variety of definitions that result in published remaining carbon budget estimates informing to cumulative emissions at the time when global-mean temperature increase would reach, exceed,

ACCEPTED VERSION SUBJECT TO FINAL EDITS

avoid, or peak at a given warming level with a given probability, for example (Collins et al., 2013a; Stocker et al., 2013c; Clarke et al., 2014; Friedlingstein et al., 2014a; IPCC, 2014; Rogelj et al., 2016; Millar et al., 2017a). This section provides an assessment of remaining carbon budgets consistent with the AR6 Glossary definition (Annex VII). Given that some feedbacks are time dependent, the values in this section apply to limiting warming over the 21st century, consistent with recent studies highlighting the usefulness of time-limited carbon budgets (Sanderson, 2020). Irrespective of the exact definition of the remaining carbon budget, the finding that higher cumulative CO_2 emissions lead to higher temperatures implies that annual net CO_2 emissions have to decline to close to zero in order to halt global warming, whether at 1.5°C, 2°C or another level (Allen et al., 2018).

Two approaches were used in AR5 to determine carbon budgets (Collins et al., 2013; Stocker et al., 2013; Clarke et al., 2014; IPCC, 2014; Rogelj et al., 2016). Working group I (WGI) reported threshold exceedance budgets (TEB) that correspond to the amount of cumulative CO_2 emissions at the time a specific temperature threshold is exceeded with a given probability in a particular greenhouse-gas and aerosol (pre-cursor) emission scenario (Collins et al., 2013a; IPCC, 2013b; Stocker et al., 2013c). WGI also reported TEBs for the hypothetical case that only CO_2 would be emitted by human activities (Collins et al., 2013a; IPCC, 2013b; Stocker et al., 2013c). AR5 Working group III used threshold avoidance budgets (TAB) that correspond to the cumulative CO_2 emissions over a given time period of a subset of greenhouse-gas and aerosol (precursor) emission scenarios in which global-mean temperature increase stays below a specific temperature threshold with at least a given probability (Clarke et al., 2014). The AR5 synthesis report used TABs defined until the time of peak warming over the 21st century (IPCC, 2014). Drawbacks have been identified for both TEBs and TABs (Rogelj et al., 2016). TABs provide an estimate of the cumulative CO_2 emissions under pathways that have as a common characteristic that they do not exceed a specific global warming threshold. The actual level of maximum warming can however vary between pathways, leading to an unnecessary and poorly constrained spread in TAB estimates (Rogelj et al., 2016). The TAB approach does therefore typically not result in accurate projections of the remaining carbon budget. On the other hand, a drawback of TEBs is that they provide an estimate of the cumulative CO_2 emissions at the time global warming crosses a given threshold of interest in a specific emissions scenario, for example, most of the standard scenarios used in climate change research such as the RCPs or SSP-based scenarios exceed global warming of 1.5°C or 2°C (see Cross-Chapter Box 1.5) (Collins et al., 2013a; Stocker et al., 2013c; Friedlingstein et al., 2014a; Millar et al., 2017a). Because of potential variations in non-CO_2 warming at that point in time or potential lags of about a decade in CO_2 warming (Joos et al., 2013; Ricke and Caldeira, 2014; Zickfeld and Herrington, 2015; Rogelj et al., 2015a, 2016, 2018) TEBs also do not provide a precise estimate of the remaining carbon budget for limiting warming to a specific level.

Since the publication of AR5 (Collins et al., 2013b), several new approaches have been proposed that provide a solution to the identified limitations of TABs and TEBs. Most of these approaches indirectly rely on the concept of TCRE (Section 5.5.1), for example, because they estimate modelled cumulative CO_2 emissions until a temperature threshold is crossed and use this budget to infer insights for pathways which attempt to limit warming to below this threshold and thus need to follow a different path (Friedlingstein et al., 2014; Matthews et al., 2017; Millar et al., 2017; Goodwin et al., 2018; Tokarska and Gillett, 2018). In this report, the assessment framework of the IPCC SR1.5 for remaining carbon budgets is applied (Rogelj et al., 2018b, 2019). This framework allows to integrate multiple lines of evidence to assess the contributions of five components that together result in a consolidated assessment of the remaining carbon budget (historical warming, TCRE, non-CO_2 warming, the ZEC, and adjustments due to additional Earth system feedbacks, see Section 5.5.2.2). It builds on the advances in estimating remaining carbon budgets or related quantities that have been published since AR5 (Rogelj et al., 2015a; Haustein et al., 2017; Matthews et al., 2017, 2021; Millar et al., 2017a; Gasser et al., 2018; Lowe and Bernie, 2018; Tokarska et al., 2018; Nicholls et al., 2020).

Recent studies suggest further changes to this framework by including non-linear adjustments to the TCRE contribution (Nicholls et al., 2020), or including non-CO_2 forcers in different ways by accounting for their different forcing effects (Matthews et al., 2021). Figure 5.31 provides a conceptual schematic of how the various individually assessed contributions are combined into a consolidated assessment of the remaining carbon budget. Together with estimates of historical CO_2 emissions to date (Section 5.2.1), these remaining carbon budgets provide the overall amount of cumulative CO_2 emissions consistent with limiting global

ACCEPTED VERSION SUBJECT TO FINAL EDITS

warming to specific levels. A comparison with the approach applied in AR5 (Collins et al., 2013; Clarke et al., 2014) is available in the IPCC SR1.5 Section 2.2.2 (Rogelj et al., 2018b) as well as Box 5.2.

[START FIGURE 5.31 HERE]

Figure 5.31: Illustration of relationship between cumulative emissions of carbon dioxide (CO_2) and global mean surface air temperature increase (left) and conceptual schematic of the assessment of the remaining carbon budget from its constituting components (right). Carbon budgets consistent with various levels of additional warming are provided in Table 5.8 and should not be read from the illustrations in either panel. Left-hand panel: Historical data (thin black line data) shows historical CO_2 emissions as reported in (Friedlingstein et al., 2020) together with the assessed global mean surface air temperature increase from 1850–1900 as assessed in Chapter 2 (Box 2.3, GSAT). The orange-brown range with its central line shows the estimated human-induced share of historical warming (Haustein et al., 2017). The vertical orange-brown line shows the assessed range of historical human-induced warming for the 2010–2019 period relative to 1850–1900 (Chapter 3). The grey cone shows the assessed range for the transient climate response to cumulative emissions of carbon dioxide (TCRE) assessed to fall *likely* in the 1.0–2.3 °C per 1000 PgC range (Section 5.5.1.4), starting from 2015. Thin coloured lines show CMIP6 simulations for the five scenarios of the AR6 core set (SSP1–1.9, green; SSP1–2.6, blue; SSP2–4.5, yellow; SSP3–7.0, red; SSP5–8.5, maroon), starting from 2015. Diagnosed carbon emissions (Arora et al., 2020) are complemented with estimated land-use change emissions for each respective scenario (Gidden et al., 2018). Coloured areas show the Chapter 4 assessed *very likely* range of GSAT projections and thick coloured central lines the median estimate, for each respective scenario, relative to the original scenario emissions (Riahi et al., 2017; Gidden et al., 2018; Rogelj et al., 2018a). Right-hand panel: schematic illustration of assessment of remaining carbon budget based on multiple lines of evidence. The remaining allowable warming is estimated by combining the global warming limit of interest with the assessed historical human induced warming (Section 5.5.2.2.2), the assessed future potential non-CO_2 warming contribution (Section 5.5.2.2.3) and the ZEC (Section 5.5.2.2.4). Note that contributions in the right-hand panel are illustrative and contributions are not to scale. For example, the central ZEC estimate was assessed to be zero. The remaining allowable warming (vertical blue bar) is subsequently combined with the assessed TCRE (Sections 5.5.1.4 and 5.5.2.2.1) and contribution of unrepresented Earth system feedbacks in models used to estimate ZEC and TCRE (Section 5.5.2.2.5) to provide an assessed estimate of the remaining carbon budget (horizontal blue bar, Table 5.8). Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

[END FIGURE 5.31 HERE]

5.5.2.2 Assessment of Individual Components

Remaining carbon budgets are assessed through the combination of five separate components (Forster et al., 2018; Rogelj et al., 2018b). Each component is discussed and assessed separately in the sections below, based on all available lines of evidence. Box 5.1 details the differences compared to AR5 and SR1.5 estimates (Collins et al., 2013b) (Rogelj et al., 2018b).

5.5.2.2.1 TCRE

The first and central component for estimating remaining carbon budgets is the TCRE. Based on the assessment in Section 5.5.1.4, an assessed *likely* range for TCRE of 1.0–2.3°C per 1000 PgC with a normal distribution is used.

5.5.2.2.2 Historical Warming

Advances in methods to estimate remaining carbon budgets have shown the importance of applying an as accurate as possible estimate of historical warming to date (Millar et al., 2017a; Tokarska and Gillett, 2018). This becomes particularly important when assessing remaining carbon budgets for global warming levels that are relatively close to present-day warming, such as a 1.5°C or 2°C levels (Rogelj et al., 2018b). Also

ACCEPTED VERSION SUBJECT TO FINAL EDITS

the definition of global average temperature by which historical warming is estimated is shown to be important (see Cross-Chapter Box 2.3) (Cowtan and Way, 2014; Allen et al., 2018; Pfleiderer et al., 2018; Richardson et al., 2018; Tokarska et al., 2019a), as is the correct isolation of human-induced global warming (Haustein et al., 2017; Allen et al., 2018) to remove the effect of internal variability. Based on the assessment in Section 3.3 (Table 3.1), we here apply an assessed best-estimate historical warming estimate expressed in global average surface air temperatures (GSAT) of 1.07°C (0.8–1.3°C, *likely* range) between 1850–1900 and 2010–2019. This choice implies global coverage and is consistent with AR5 where carbon budgets were reported in GSAT (Collins et al., 2013a; Stocker et al., 2013c), the SR1.5 where GSAT was the central metric for remaining carbon budgets (Rogelj et al., 2018b) and recent studies that highlight how GSAT enables an easy translation with AR5 (Tokarska et al., 2019a). The use of other historical reference periods (Cross-Chapter Box 1.2) or temperature metrics and updated data products (Cross-Chapter Box 2.3) can result in a different estimated historical warming and thus a changed remaining carbon budget.

5.5.2.2.3 Non-CO2 Warming Contribution

Non-CO_2 emissions contribute either cumulatively (N_2O, and other long-lived climate forcers) or in proportion to their annual emissions (CH_4 and other short-lived climate forcers) to global warming, and thus also affect estimates of remaining carbon budgets by reducing the amount of warming that could still result from CO_2 emissions (Meinshausen et al., 2009; Friedlingstein et al., 2014a; Knutti and Rogelj, 2015; Rogelj et al., 2015a, 2016, Williams et al., 2017c, 2016; Matthews et al., 2017; Collins et al., 2018; Mengis et al., 2018; Tokarska et al., 2018; Zickfeld et al., 2021). The size of this contribution has been estimated both implicitly (Meinshausen et al., 2009; Friedlingstein et al., 2014a; Rogelj et al., 2016; Matthews et al., 2017; Mengis et al., 2018; Tokarska et al., 2018) and explicitly (Rogelj et al., 2015a, 2018b; Collins et al., 2018; Matthews et al., 2021) by varying the assumptions of non-CO_2 emissions and associated warming. Internally consistent evolutions of future CO_2 and non-CO_2 emissions allow to derive non-CO_2 warming contributions consistent with global CO_2 emissions reaching net zero levels and therewith capping maximum future CO_2 emissions (Smith and Mizrahi, 2013; Clarke et al., 2014; Huppmann et al., 2018; Rogelj et al., 2018b; Matthews et al., 2021). Pathways that reflect such development typically show a stabilisation or decline in non-CO_2 radiative forcing and warming at and after the time of global CO_2 emissions reaching net zero levels, as illustrated in the scenario database underlying the IPCC SR1.5 (Huppmann et al., 2018; Rogelj et al., 2018b).

The impact of non-CO_2 emissions on remaining carbon budgets is assessed with emulators (Meinshausen et al., 2009; Millar et al., 2017a; Gasser et al., 2018; Goodwin et al., 2018; Rogelj et al., 2018b; Smith et al., 2018a; Matthews et al., 2021) that incorporate synthesised climate and carbon-cycle knowledge (Cross-Chapter Box 7.1). The estimated implied non-CO_2 warming can subsequently be applied to reduce the remaining allowable warming for estimating the remaining carbon budget (see Figure 5.31) (Rogelj et al., 2018b, 2019). Alternative methods estimate the non-CO_2 fraction of total anthropogenic forcing (Matthews et al., 2021), or do not correct for non-CO_2 warming directly. The latter methods instead consider CO_2 and non-CO_2 warming together to define a CO_2 forcing equivalent carbon budget from which eventual non-CO_2 contributions expressed in CO_2-forcing-equivalent emissions have to be subtracted to obtain a remaining carbon budget (Jenkins et al., 2018; Matthews et al., 2020). These studies also use emulators to invert a specified evolution of non-CO_2 forcing to a corresponding amount of equivalent CO_2 emissions (Matthews et al., 2020), or alternatively use empirical relationships linking changes in non-CO_2 greenhouse gas emissions to warming (Cain et al., 2019). Methods to express non-CO_2 emissions in CO_2 equivalence are assessed in Section 7.6, yet their applicability and related uncertainties for remaining carbon budgets have not yet been covered in-depth in the literature.

Application of the SR1.5 method (Forster et al., 2018; Rogelj et al., 2018b) with AR6-calibrated emulators (Box 7.1) suggests a median additional non-CO_2 warming contribution at the time global CO_2 emissions reach net zero levels of about 0.1–0.2°C relative to 2010–2019. Uncertainty surrounding this range due to geophysical uncertainties such as non-CO_2 forcing uncertainties and TCR is of the order of ±0.1°C. Differences in the choices of mitigation strategies considered in low-emission scenarios (Huppmann et al., 2018) result in a potential additional variation around the central range of at least ±0.1°C (spread across scenarios, referred to as non-CO_2 scenario uncertainty in Table 5.8).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

5.5.2.2.4 Adjustments due to the Zero-Emission Commitment (ZEC)

Use of TCRE for estimating remaining carbon budgets needs to consider the ZEC, the potential additional warming after a complete cessation of net CO_2 emissions. Based on the ZEC assessment presented in Section 4.7.2, the ZEC's central value is taken to be zero with a *likely* range of ±0.19°C, noting that it might either increase or decrease after half a century. ZEC uncertainty is assessed for a time frame of half a century, as this most appropriately reflects the time between the time stringent mitigation pathways reach net zero CO_2 emissions and the end of the century. For shorter time horizons, a similar central zero value applies, but with a smaller range (MacDougall et al., 2020). Experiments that ramped up and down emissions following a bell-shaped trajectory (MacDougall and Knutti, 2016a) show that when annual CO_2 emissions decline to zero at a pace consistent with those currently assumed in mitigation scenarios (Huppmann et al., 2018; Rogelj et al., 2018b), the ZEC will already be realised to a large degree at the time of reaching net zero CO_2 emissions (MacDougall et al., 2020).

5.5.2.2.5 Adjustments for Other not Represented Feedbacks

Section 5.5.1.2 highlighted recent literature describing potential impacts of Earth system feedbacks that have typically not been included in standard ESMs (Schneider von Deimling et al., 2015; MacDougall and Friedlingstein, 2015; Schädel et al., 2016; Burke et al., 2017; Mahowald et al., 2017; Comyn-Platt et al., 2018; Gasser et al., 2018; Lowe and Bernie, 2018), the most important of which is carbon release from thawing permafrost. The IPCC SR1.5 estimated unrepresented Earth system processes to result in a reduction of remaining carbon budgets of up to 100 $GtCO_2$ over the course of this century, and more thereafter (Rogelj et al., 2018b). Here this assessment is updated based on the Earth system feedback assessment of Section 5.4.8 and synthesised in Figure 5.29 by applying the reverse method by (Gregory et al., 2009).

The assessment in Section 5.4 and Box 5.1 highlights the different nature, magnitude and uncertainties surrounding additional Earth system feedback. The remaining carbon budgets reported in Table 5.8 account for these feedbacks, including corrections due to permafrost CO_2 and CH_4 feedbacks as well as those due to aerosol and atmospheric chemistry (Section 5.4.8). Two of these additional feedbacks (tropospheric ozone and methane lifetime feedbacks) are included in the projections of non-CO_2 warming carried out with AR6-calibrated emulators (Box 7.1). The remainder of these independent Earth system feedbacks combine to a feedback of about 7 ± 27 PgC K^{-1} (1-sigma range, or 26 ± 97 $GtCO_2$ $°C^{-1}$). Overall, Section 5.4.8 assessed there to be *low confidence* in the exact magnitude of these feedbacks and they represent identified additional amplifying factors that scale with additional warming and mostly increase the challenge of limiting global warming to or below specific temperature levels.

5.5.2.3 Remaining Carbon Budget

The combination of the five components assessed in Sections 5.5.2.2.1–5.5.2.2.5 allows for an overall assessment of the remaining carbon budget in line with different levels of global average warming, as documented in the IPCC SR1.5 (Rogelj et al., 2018b). The overall assessment of remaining carbon budgets (Table 5.8) reflects the uncertainty in TCRE quantification and provides estimates of the uncertainties surrounding the contributions of each of the respective further components. A formal combination of all uncertainties is not possible because they are not all independent or because they represent choices rather than probabilistic uncertainties (Matthews et al., 2021). In light of all uncertainties related to TCRE, non-CO_2 forcing and response, the level of non-CO_2 mitigation, and historical warming, there is a small probability that the remaining carbon budget for limiting warming to 1.5°C since the 1850–1900 period is effectively zero. However, applying best estimate values for all but uncertainties in Earth system feedbacks and TCRE, the remaining carbon budgets in line with the Paris Agreement are generally small yet not zero (see Table 5.8).

There is *robust evidence* supporting the concept of TCRE as well as *high confidence* in the range of historical human-induced warming. Combined with the assessed uncertainties in the Earth system's response

ACCEPTED VERSION SUBJECT TO FINAL EDITS

to non-CO_2 emissions and less well-established quantification of some of the effect of non-linear Earth system feedbacks, this leads to *medium confidence* being assigned to the assessed remaining carbon budget estimates while noting the identified and assessed uncertainties and potential variations. The reported values are applicable to warming and cumulative emissions over the 21st century. For climate stabilisation beyond the 21st century this confidence would decline to *very low confidence* due to uncertainties in Earth system feedbacks and the ZEC.

For estimates of total carbon budgets in line with limiting global warming to a specific level, an estimate of historical CO_2 emissions should be added to the remaining carbon budget values reported in Table 5.8. Historical CO_2 emissions between 1850 and 2019 have been estimated at about 655 ± 65 PgC (1-sigma range, or 2390 ± 240 $GtCO_2$, see Table 5.1), while since 1 January 2015, an additional 57 PgC (210 $GtCO_2$) has been emitted until the end of 2019 (Friedlingstein et al., 2020).

[START TABLE 5.8 HERE]

Table 5.8: The assessed remaining carbon budget and corresponding uncertainties. Assessed estimates are provided for additional human-induced warming expressed as global average surface air temperature since the recent past (2010–2019), which *likely* amounted to 0.8 to 1.3 with a best estimate of 1.07°C relative to 1850–1900 (Table 3.1 in Chapter 3).

1.33	2.4	*920 (3350)*	*680 (2500)*	*550 (2050)*	*470 (1700)*	*380 (1400)*					

*(1) Human-induced global surface air temperature increase between 1850–1900 and 2010–2019 is assessed at 0.8–1.3°C (*likely* range; Chapter 3) with a best estimate of 1.07°C. Warming here reflects GSAT, as TCRE and other estimates are GSAT based. Combined with a central estimate of TCRE (1.65 °C EgC^{-1}) the uncertainty in historical human-induced GSAT warming results in a potential variation of remaining carbon budgets of ±150 PgC or ±550 $GtCO_2$.

*(2) Historical CO_2 emissions between 1850 and 2019 have been estimated at about 655 ± 65 PgC (1-sigma range, or 2390 ± 240 $GtCO_2$, see Table 5.1). Note that 57 PgC (210 $GtCO_2$) have been emitted from the middle of the 2010-2019 reference period (2015) until the end of 2019 (Friedlingstein et al., 2020).

*(3) TCRE: transient climate response to cumulative emissions of carbon, assessed to fall *likely* between 1.0–2.3 °C EgC^{-1} with a normal distribution. PgC values are rounded to the nearest 10; $GtCO_2$ values to the nearest 50. For comparison, assuming a lognormal distribution with a 1.0–2.3 °C EgC^{-1} central 66% range instead of a normal distribution would increase remaining carbon budgets at the 17th, 33rd, 50th, 67th, and 83rd percentile with 3%, 10%, 12%, 9%, 2%, respectively. Future non-CO_2 contributions in these remaining carbon budget estimates are based on the scenarios assessed in the IPCC SR1.5 report and estimated as the median quantile regression of non-CO_2 warming since 2010–2019 relative to total additional warming since 2010–2019 at the time scenarios reach net-zero CO_2 emissions (Forster et al., 2018; Huppmann et al., 2018; Rogelj et al., 2018b).

*(4) Additional Earth system feedbacks are included in the remaining carbon budget estimates as discussed in Section 5.5.2.2.5. The tropospheric ozone and methane lifetime contributions are included through the non-CO_2 warming projections by the AR6-calibrated MAGICC emulator, while the remaining feedbacks are assessed totalling a combined feedback of magnitude 7 ± 27 PgC K^{-1} (1-sigma range, or 26 ± 97 $GtCO_2$ $°C^{-1}$).

*(5) Variations due to different scenario assumptions related to the future evolution of non-CO_2 emissions in mitigation scenarios reaching net zero CO_2 emissions (Huppmann et al., 2018; Rogelj et al., 2018b) of at least ±0.1°C (spread across scenarios). Combined with a central estimate of TCRE (1.65 °C EgC^{-1}) this results in at least ±60 PgC or ±220 $GtCO_2$. This spread reflects the variation in the underlying scenario ensemble but is not a formal likelihood. WGIII will reassess the potential for non-CO_2 mitigation based on literature since the SR1.5.

*(6) Remaining carbon budget variation due to geophysical uncertainty in forcing and temperature response of non-CO_2 emissions of the order of ±0.1°C, very largely range (5–95%) of non-CO_2 response (Section 5.5.2.2.3). Combined with a central estimate of TCRE (1.65 °C EgC^{-1}) this results in at least ±60 PgC or ±220 $GtCO_2$.

*(7) The variation due to the ZEC is estimated for a central TCRE value of 1.65 °C EgC^{-1} and a 1-sigma ZEC range of 0.19°C. In real-world pathways, the magnitude of this effect will depend on the pace of CO_2 emissions reductions to net zero.

[START BOX 5.2 HERE]

BOX 5.2: Implications of methodological advancements in estimating the remaining carbon budget since AR5

Methodological advancements since the IPCC AR5 (Collins et al., 2013; IPCC, 2013; Clarke et al., 2014; IPCC, 2014; Stocker et al., 2013) result in an updated and strengthened assessment of remaining carbon budgets. Methods and approaches at the time of AR5 are described in Section 5.5.2.1. Since AR5, strengths and weaknesses of various approaches have been more clearly articulated in the literature (e.g., in (Rogelj et al., 2016; Millar et al., 2017a; Tokarska and Gillett, 2018; Matthews et al., 2020)), resulting in a new consolidated framework applied in SR1.5 (Rogelj et al., 2018b, 2019) that is also used in AR6. This framework incorporates five methodological advancements compared to AR5, the implications of which are discussed in this box.

First, publications since AR5 applied methods that limit the effect of uncertainties in historical, diagnosed emissions in coupled Earth system models on estimates of the remaining carbon budget (Millar et al., 2017a; Tokarska and Gillett, 2018). These new methods express remaining carbon budget estimates relative to a recent reference period instead of relative to pre-industrial (Millar et al., 2017a; Tokarska et al., 2019a). Estimates of the full carbon budget since pre-industrial can still be obtained by adding estimates of historical CO_2 emissions (Table 5.1) to estimates in Table 5.8. This methodological update resulted, all other aspects being equal, in median estimates of remaining carbon budgets being about 350–450 $GtCO_2$ larger compared to AR5 (IPCC, 2014; Millar et al., 2017a).

At the time of the AR5, CMIP5 (Taylor et al., 2012) provided global mean surface air temperature (GSAT) projections for the representative concentration pathways (Meinshausen et al., 2011b), which were used to determine carbon budgets while taking into account the effects of non-CO_2 forcers (Stocker et al., 2013c). Their use came with two recognised limitations: first, the model spread of the CMIP5 ensemble represents an ensemble of opportunity with limited statistical value (Tebaldi and Knutti, 2007); and second, the evolution of non-CO_2 emissions as a function of cumulative CO_2 emissions can differ markedly between high and low emissions pathways (Meinshausen et al., 2011a; Rogelj et al., 2016; Friedlingstein et al., 2014; Matthews et al., 2017). Solutions to these two limitations have been published since AR5 and represent the second and third methodological improvement compared to AR5.

The reliance on an ensemble of opportunity (i.e. a serendipitous collection of scenario data from a variety of sources and studies) is avoided by methodologically separating the assessment of future warming contributions of non-CO_2 emissions from the spread in TCRE (Rogelj et al., 2018b, 2019) (see Section 5.5.2). This facilitates the explicit representation of TCRE uncertainty by a formal distribution, in this case a normal distribution with a 1.0–2.3°C PgC^{-1} 1–sigma range (Section 5.5.1.4). The effect of this methodological advance can be estimated from a direct comparison of the frequency distribution of TCRE in CMIP5 models that were used in AR5 and the formal TCRE distribution used in AR6, but is limited in precision. For estimates of the remaining carbon budget in line with limiting warming to 1.5°C or 2°C relative to pre-industrial levels, this improvement is estimated to lead to a reduction of budgets of the order of about 100 $GtCO_2$ between AR5 and AR6.

The third methodological improvement is a more direct estimation of the warming contribution of non-CO_2 emissions, consistent with pathways that bring global CO_2 emissions down to net zero. Instead of deriving this contribution implicitly from the CMIP5 ensemble, climate emulators (Meinshausen et al., 2011c; Schwarber et al., 2018; Smith et al., 2018b) that are calibrated to the combined AR6 assessment (Cross-Chapter Box 7.1) are used to estimate the non-CO_2 contribution across a wide variety of stringent mitigation

ACCEPTED VERSION SUBJECT TO FINAL EDITS

scenarios (Huppmann et al., 2018). The specific relative effect of this advance compared to AR5 is not calculable because CMIP5 data does not isolate non-CO_2 from CO_2-induced warming.

The fourth and fifth methodological advancements are to explicitly account for the zero-emission commitment (ZEC, Section 5.5.2.2.4) and adjust estimates for Earth system feedbacks that are typically not represented in Earth System models (Section 5.5.2.2.5). The central estimate of the assessed ZEC used in SR1.5 and AR6 is zero (Sections 4.7.2). ZEC uncertainties are reported separately (Table 5.8), and the additional consideration of ZEC therefore does result in a better understanding but not in a net shift of central estimates of the remaining carbon budget compared to AR5. Furthermore, AR5 did not explicitly account for Earth system feedbacks not represented in Earth system models. SR1.5 assessed that they could reduce the remaining carbon budgets by about 100 $GtCO_2$ over centennial timescales. This assessment has been updated in AR6, including a wider range of biogeochemical feedbacks and new evidence (Section 5.5.2.2.5). Some of these feedbacks are captured in the estimation of non-CO_2 warming (see below), while the combined effect of remaining positive and negative feedbacks is assessed to reduce the remaining carbon budget estimates by 7 ± 27 PgC K^{-1} (1-sigma range, or 26 ± 97 $GtCO_2$ $°C^{-1}$) compared to AR5.

Between SR1.5 and AR6, each of the five components described in Section 5.5.2.1 and Figure 5.32 have been re-assessed (see Sections 5.5.2.2.1 to 5.5.2.2.5). Their updated assessments in turn affect the assessment of the remaining carbon budget. The new and narrower assessment of TCRE in AR6 compared to SR1.5 (*likely* range of 1.0–2.3°C EgC^{-1} compared to 0.8–2.5°C EgC^{-1}, respectively, with the same central estimate) leads to no change in median estimates and about a 50 and 100 $GtCO_2$ increase in remaining carbon budgets estimates at the 67th percentile in AR6 compared to SR1.5 for 1.5°C and 2°C of global warming, respectively.

For historical warming, SR1.5 used GSAT increase between 1850–1900 and 2006–2015 of 0.97°C as its main starting point, while also providing values for other temperature metrics. Remaining carbon budgets were expressed starting from 1 January 2018 by accounting for historical emissions emitted from 1 January 2011 until the end of 2017. AR6 uses anthropogenic (human-induced) warming until the 2010–2019 period, which is assessed at the 0.8-1.3°C range, with a best estimate of 1.07°C (Table 3.1), and subsequently accounts for historical emissions from 1 January 2015 until the end of 2019 to express remaining carbon budget estimates from 1 January 2020 onwards. The human-induced warming between the 1850–1900 and 2006–2015 periods used in SR1.5 was assessed by AR6 at 0.97°C (Table 3.1). In a like-with-like comparison, the combined effect of data and methodological updates in historical warming estimates thus results in no shift in estimated remaining carbon budgets between SR1.5 and AR6. However, the emissions of the years passed since SR1.5 reduce the remaining carbon budget by about 85 $GtCO_2$. Note that AR6 also updated its GSAT assessment for total warming between the 1850–1900 and 2006–2015 periods, reporting 0.94°C of warming. On a like-with-like basis, this would have resulted in slightly larger remaining carbon budgets compared to SR1.5 (Cross-Chapter Box 2.3).

The non-CO_2 contribution to future warming in emissions scenarios (Huppmann et al., 2018) is re-assessed with AR6-calibrated emulators, in this case MAGICC7 (Meinshausen et al., 2009, 2011a, 2020) (Cross-Chapter Box 7.1). The re-assessment of non-CO_2 warming with MAGICC7 results in a relationship that closely matches the average relationship applied in SR1.5 (shown in Section 2.SM.1.1.2 in (Forster et al., 2018)), and does therefore not change estimates of the remaining carbon budget relative to SR1.5. The median ZEC assessment remained the same between SR1.5 and AR6, and therefore also does not change the median remaining carbon budget estimates. Finally, as indicated above, AR6 expanded the assessment of Earth system feedbacks compared to SR1.5 and included it in its central remaining carbon budget estimates. Some feedbacks are accounted for through the non-CO_2 warming estimate (Section 5.5.2.2.5), while the remainder combines to reduce the median remaining carbon budget estimates for 1.5°C and 2°C of warming by about 10 to 20 $GtCO_2$, respectively, compared to SR1.5.

All methodological improvements and new evidence combined result in median and 67th percentile remaining carbon budget estimates for limiting warming to 1.5°C being about 300–350 $GtCO_2$ larger compared to an assessment that would use the evidence and methods available at the time of the AR5. For limiting warming to 2°C, the difference is about 400–500 $GtCO_2$. Since SR1.5, fewer key advancements had

ACCEPTED VERSION SUBJECT TO FINAL EDITS

to be integrated. In a like-with-like comparison, the combined effects of all AR6 updates result in median remaining carbon budget estimates for limiting warming to 1.5°C and 2°C being the same and about 60 $GtCO_2$ smaller, respectively, in AR6 compared to SR1.5. At the 67th percentile, remaining carbon budget estimates for limiting warming to 1.5°C and 2°C are about 40 to 60 $GtCO_2$ larger, respectively, mainly as a result of a narrower assessed TCRE range.

[END BOX 5.2 HERE]

5.6 Biogeochemical Implications of Carbon Dioxide Removal and Solar Radiation Modification

5.6.1 Introduction

Carbon dioxide removal (CDR) refers to anthropogenic activities that seek to remove CO_2 from the atmosphere and durably store it in geological, terrestrial or ocean reservoirs, or in products (Glossary, Annex VII). CO_2 is removed from the atmosphere by enhancing biological or geochemical carbon sinks or by direct capture of CO_2 from air and storage. Solar radiation modification (SRM), on the other hand, refers to the intentional, planetary-scale modification of the Earth's radiative budget with the aim of limiting global warming. Most proposed SRM methods involve reducing the amount of incoming solar radiation reaching the surface, but others also act on the longwave radiation budget by reducing optical thickness and cloud lifetime (Glossary, Annex VII). SRM does not fall within the IPCC definitions of mitigation and adaptation (Glossary, Annex VII). CDR and SRM are referred to as 'geoengineering' in some of the literature and are considered separately in this report.

This section assesses the implications of CDR and SRM for biogeochemical cycles. CDR has received growing interest as an important mitigation option in emission scenarios consistent with meeting the Paris Agreement climate goals (SR1.5, SRCCL). The climate effects of CDR and SRM are assessed in Chapter 4, and a detailed assessment of the socio-economic dimensions of these options is presented in AR6 WGIII, Chapters 7 and 12.

5.6.2 Biogeochemical Responses to Carbon Dioxide Removal (CDR)

The scope of this section is to assess the general and methods-specific effects of CDR on the global carbon cycle and other biogeochemical cycles. The focus is on Earth system feedbacks that either amplify or reduce carbon sequestration potentials of specific CDR methods, and determine their effectiveness in reducing atmospheric CO_2 and mitigating climate change. Technical carbon sequestration potentials of CDR methods are assessed on a qualitative scale; a comprehensive quantitative assessment is left to the AR6 Working Group III report (Chapters 7 and 12). Biogeochemical and biophysical side effects of CDR methods are assessed here while the co-benefits and trade-offs for biodiversity, water and food production are briefly discussed for completeness, but a comprehensive assessment is left to WGII (Chapters 2 and 5) and WGIII (Chapters 7 and 12). The assessment in this chapter emphasises literature published since the AR5 WGI report (Chapter 6) for the assessment of the global carbon cycle response to CDR, and literature published since the IPCC SR1.5 (Chapter 4; IPCC, 2018), SRCCL (Chapter 6, IPCC, 2019) and SROCC (Bindoff et al., 2019) for the assessment of potentials and side effects of specific CDR methods. Emerging literature on deliberate methane removal is also briefly discussed.

In this chapter, CDR methods are categorised by the carbon cycle processes that result in CO_2 removal: (i) enhanced net biological production and storage by land ecosystems, (ii) enhanced net biological production and storage in the open and coastal ocean, (iii) enhanced geochemical processes on land and in the ocean, and (iv) direct air capture and storage by chemical processes. A subset of CDR methods that restore or sustainably manage natural or modified ecosystems while providing human well-being and biodiversity benefits are also referred to as natural or nature-based solutions (see Glossary, Annex VII) (Griscom et al., 2017, 2020; Fargione et al., 2018). CDR methods commonly discussed in the literature are summarised in Table 5.9. Other CDR options have been suggested, but there is insufficient literature for an assessment.

ACCEPTED VERSION SUBJECT TO FINAL EDITS

These include ocean biomass burial, ocean downwelling, removal of CO_2 from seawater with storage, and cloud alkalinisation (Keller et al., 2018a; GESAMP, 2019).

[START TABLE 5.9 HERE]

Table 5.9: Characteristics of carbon dioxide removal (CDR) methods. Termination effects refer to the possible effects of a hypothetical, sudden and sustained termination of the CDR method.

Category	Methods (subsection where the method is assessed)	Nature of CO_2 Removal Process / Storage Form	Description	Time scale of carbon storage	Factors that affect carbon storage time scale	Termination effects
Enhanced biological production and storage on land (in vegetation, soils or geologic formations)	Afforestation, reforestation and forest management (5.6.2.2.1)	Biological / Organic	Store carbon in trees and soils by planting, restoring or managing forests	Decades to centuries (Cooper, 1983)	Disturbances (e.g., fires, pests), extreme weather	None
	Soil carbon sequestration (5.6.2.2.1)	Biological / Organic	Use agricultural management practices to improve soil carbon storage	Decades to centuries (Dignac et al., 2017)	Soil and crop management.	None
	Biochar (5.6.2.2.1)	Biological / Organic	Burn biomass at high temperature under anoxic conditions to form biochar and add to soils	Decades to centuries (Campbell et al., 2018)	Fire	None
	Peatland restoration (5.6.2.2.1)	Biological / Organic	Store carbon in soil by creating or restoring peatlands	Decades to centuries (Harenda et al., 2018)	Peatland drainage, fire, drought, land use change	None
	Bioenergy with carbon capture and storage (BECCS) (5.6.2.2.1)	Biological / Inorganic	Production of energy from plant biomass combined with carbon capture and storage	Potentially permanent (analogous to DACCS) (Szulczewski et al., 2012)	Leakage	None
Enhanced biological production and storage in coastal and open ocean	Ocean fertilisation (5.6.2.2.2)	Biological / organic	Fertilise upper ocean with micro (Fe) and macronutrients (N, P) to increase phytoplankton photosynthesis and biomass and deep ocean carbon storage through the biological	Decades to millennia (Oschlies et al., 2010; Robinson et al., 2014)	Ocean stratification and circulation (Robinson et al., 2014); efficiency of carbon sequestration in deep ocean(Yoon et al., 2018)	Uncertain (Keller et al., 2014)

ACCEPTED VERSION SUBJECT TO FINAL EDITS

			pump			
	Artificial ocean upwelling (5.6.2.2.2)	Biological / organic	Pump nutrient-rich deep ocean water to the surface to increase carbon uptake and storage through the biological pump.	Centuries to millennia (Oschlies et al., 2010b)	Ocean circulation; DIC content of upwelled waters (Oschlies et al., 2010c)	Warming beyond temperatures experienced if artificial ocean upwelling had not been deployed (Keller et al., 2014)
	Restoration of vegetated coastal ecosystems ("blue carbon") (5.6.2.2.2)	Biological / organic	Manage coastal ecosystems to increase net primary production and store carbon in sediments	Decades to centuries if functional integrity of ecosystem maintained (Mcleod et al., 2011)	Land use change of coastal ecosystems; extreme weather (e.g., heatwaves); sea level change (NASEM, 2019)	None
Enhanced geochemical processes on land and in ocean	Enhanced weathering (5.6.2.2.3)	Geochemical / inorganic	Spread alkaline minerals on land to chemically remove atmospheric CO_2 in reactions that form solid minerals (carbonates and silicates) that are stored in soils or in the ocean	10,000 to 10^6 years (Fuss et al., 2018)	Storage in soils or ocean (Fuss et al., 2018)	None
	Ocean alkalinisation (5.6.2.2.3)	Geochemical / inorganic	Increased CO_2 uptake via increased alkalinity by deposition of alkaline minerals (e.g. olivine).	10,000 to 100,000 years (Keller, 2019)	Carbonate chemistry; ocean stratification and circulation (Keller, 2019)	Higher rates of warming and acidification than if alkalinisation not begun (under a high emissions scenario) (González et al., 2018)
Chemical	Direct air carbon capture with storage (DACCS) (5.6.2.2.4)	Chemical / inorganic	Direct removal of CO_2 from air through chemical adsorption, absorption or mineralisation, and storage underground,	Potentially permanent	Leakage	None

5.6.2.1 Global Carbon Cycle Responses to CDR

This subsection assesses evidence about the response of the global carbon cycle to CDR from idealised model simulations which assume that CO_2 is removed from the atmosphere directly and stored permanently in the geologic reservoir, which is analogous to direct air carbon capture with carbon storage (DACCS; Table 5.9). The carbon cycle response to specific land and ocean-based CDR methods is assessed in Section 5.6.2.2.2. At the time of AR5 there were very few studies about the global carbon cycle response to CDR. Based on these studies and general understanding of the carbon cycle, AR5 WGI Chapter 6 assessed that it is *virtually certain* that deliberate removal of CO_2 from the atmosphere will be partially offset by outgassing of CO_2 from the ocean and land carbon sinks. *Low confidence* was placed on any quantification of effects. Since the WGI AR5 (Chapter 6), several studies have investigated the carbon cycle response to CDR in idealised "pulse" removal simulations, whereby a specified amount of CO_2 is removed instantly from the atmosphere, and scenario simulations with CO_2 emissions and removals following a plausible trajectory. In addition, a dedicated carbon dioxide removal model intercomparison project (CDRMIP) (Keller et al., 2018b) was initiated, which includes a range of CDR experiments from idealised simulations to simulations of deployment of specific CDR methods (afforestation and ocean alkalinisation).

This subsection assesses three aspects of the climate-carbon cycle response to CDR: the time-dependent behaviour of CO_2 fluxes in scenarios with CDR, the effectiveness of CDR in drawing down atmospheric CO_2 and cooling global mean temperature, and the symmetry of the climate-carbon cycle response to positive and negative CO_2 emissions.

[START BOX 5.3 HERE]

BOX 5.3: Carbon cycle response to CO_2 removal from the atmosphere

During the industrial era, CO_2 emitted by the combustion of fossil fuels and land-use change has been redistributed between atmosphere, land, and ocean carbon reservoirs due to carbon cycle processes (Box 5.3 Figure 1b; Figure 5.13). Over the past decade (2010–2019), 46% of the emitted CO_2 remained in the atmosphere, 23% was taken up by the ocean and 31% by the terrestrial biosphere (Section 5.2.1.5). When carbon dioxide removal (CDR) is applied during periods in which human activities are net CO_2 sources to the atmosphere and the amount of emissions removed by CDR is smaller than the net source (net positive CO_2 emissions), CDR acts to reduce the net emissions (Box 5.3 Figure 1c). In this scenario part of the CO_2 emissions into the atmosphere is removed by the land and ocean sinks, as has been the case historically.

When CDR removes more CO_2 emissions than human activities emit (net negative CO_2 emissions), and atmospheric CO_2 declines, the land and ocean sinks initially continue to take up CO_2 from the atmosphere. This because carbon sinks, particularly the ocean, exhibit inertia and continue to respond to the prior trajectory of rising atmospheric CO_2 concentration. After some time, which is determined by the magnitude of the removal and the rate and amount of CO_2 emissions prior to the CDR application, land and ocean carbon reservoirs begin to release CO_2 to the atmosphere making CDR less effective (Box 5.3 Figure 1d).

[START BOX 5.3, FIGURE 1 HERE]

Box 5.3, Figure 1: Schematic representation of carbon fluxes between atmosphere, land, ocean and geological

ACCEPTED VERSION SUBJECT TO FINAL EDITS

reservoirs. Different system conditions are shown: (a) an unperturbed Earth system; and changes in carbon fluxes for (b) an Earth system perturbed by fossil-fuel CO_2 emissions, (c) an Earth system in which fossil-fuel CO_2 emissions are partially offset by CDR, (d) an Earth system in which CDR exceeds CO_2 emissions from fossil fuels ("net negative" CO_2 emissions). Carbon fluxes depicted in (a) (solid and dashed black lines) also occur in (b)-(d). The question mark in the land-to-ocean carbon flux perturbation in (c) and (d) indicates that the effect of CDR on this flux is unknown. Note that box sizes do not scale with the size of carbon reservoirs. Adapted from (Keller et al., 2018a). Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

[END BOX 5.3 HERE]

5.6.2.1.1 Carbon Cycle Response to Instantaneous CDR

Idealised "pulse" removal Earth system model simulations are useful for understanding the carbon cycle response to CDR. Figure 5.32 illustrates the response of atmospheric CO_2, land and ocean carbon sinks to an instantaneous CO_2 removal applied from a pre-industrial equilibrium state. Following CO_2 removal from the atmosphere, the atmospheric CO_2 concentration declines rapidly at first and then rebounds (Figure 5.32 a). This rebound is due to CO_2 release by the terrestrial biosphere and the ocean in response to declining atmospheric CO_2 levels (Figure 5.32 b, c) (Collins et al., 2013a). For the model simulations shown in Figure 5.32, 23 ± 6% (mean ± 1 standard deviation) of the 100 PgC removed remains out of the atmosphere 80–100 years after the instantaneous removal. The remainder is offset by CO_2 outgassing from the land (49 ± 12%) and ocean (29 ± 7%). While the direction of the CO_2 flux is robust across models, the relative contribution of the outgassing from land and ocean reservoirs to the atmospheric CO_2 rebound after removal varies. These results corroborate the *high confidence* placed by WGI AR5 Chapter 6 on the partial compensation of CO_2 removal from the atmosphere by CO_2 outgassing from the land and ocean. Due to disagreement between models, the magnitude of this outgassing and in the relative contribution of land and ocean fluxes remains *low confidence*.

[START FIGURE 5.32 HERE]

Figure 5.32: Carbon cycle response to instantaneous carbon dioxide (CO_2) removal from the atmosphere. (a) Atmospheric CO_2 concentration, (b) change in land carbon reservoir, (c) change in ocean carbon reservoir. Results are shown for simulations with seven CMIP6 Earth system models and the UVic ESCM model of intermediate complexity forced with 100 PgC instantaneously removed from the atmosphere. The 'pulse' removal is applied from a model state in equilibrium with a pre-industrial atmospheric CO_2 concentration (CDRMIP experiment CDR-pi-pulse; Keller et al., 2018b). Changes in land and ocean carbon reservoirs are calculated relative to a pre-industrial control simulation. Data for the UVic ESCM is from Zickfeld et al. (2021). Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

[END FIGURE 5.32 HERE]

5.6.2.1.2 Carbon Cycle Response Over Time in Scenarios with CDR

Since WGI AR5 (Chapter 6), studies with ESMs have explored the land and ocean carbon sink response to scenarios with CO_2 emissions gradually declining during the 21st century. As CDR and other mitigation activities are ramped up, CO_2 emissions in these scenarios reach net zero and, as removals exceed emissions, become net negative. Studies exploring the carbon sink response to such scenarios (e.g. RCP2.6, SSP1–2.6) show that when net CO_2 emissions are positive, but start to decline, uptake of CO_2 by the land and ocean begins to weaken (compare land and ocean CO_2 fluxes in panels (a) and (b) of Figure 5.33) (Tokarska and Zickfeld, 2015; Jones et al., 2016b). During the first decades after CO_2 emissions become net negative, both the ocean and land carbon sinks continue to take up CO_2, albeit at a lower rate. For the land carbon sink, the sink-to-source transition occurs decades to a century after CO_2 emissions become net negative (Figure

ACCEPTED VERSION SUBJECT TO FINAL EDITS

5.33c). The ocean remains a sink of CO_2 for centuries after emissions become net negative (Figure 5.33c-e; Section 5.4.9; Figure 5.30). Whether the transition to source occurs at all, the timing of the transition and the magnitude of the CO_2 source are determined by the magnitude of the removal and the rate and amount of net CO_2 emissions prior to emissions becoming net negative (*medium confidence*) (Tokarska and Zickfeld, 2015; Jones et al., 2016b). For scenarios with large amounts of CO_2 removal such as SSP5–3.4–overshoot the land source is larger than for SSP1–2.6 and the ocean also turns into a source (Section 5.4.10, Figure 5.30). While the qualitative response to scenarios with net-negative emissions is largely robust across models, the timing of the sink-to-source transition and the magnitude of the CO_2 source vary between models, particularly for the land sink. Due to *limited agreement* between models there is *low confidence* in the timing of the sink-to-source transition and the magnitude of the CO_2 source in scenarios with net-negative CO_2 emissions.

[START FIGURE 5.33 HERE]

Figure 5.33: Carbon sink response in a scenario with net carbon dioxide (CO_2) removal from the atmosphere. Shown are CO_2 flux components from concentration-driven Earth system model simulations during different emission stages of SSP1–2.6 and its long-term extension. (a) Large net positive CO_2 emissions, (b) small net positive CO_2 emissions, (c) – (d) net negative CO_2 emissions, (e) net zero CO_2 emissions. Positive flux components act to raise the atmospheric CO_2 concentration, whereas negative components act to lower the CO_2 concentration. Net CO_2 emissions, land and ocean CO_2 fluxes represent the multi-model mean and standard deviation (error bar) of four ESMs (CanESM5, UKESM1, CESM2-WACCM, IPSL-CM6a-LR) and one EMIC (UVic ESCM; (Mengis et al., 2020)). Net CO_2 emissions are calculated from concentration-driven Earth system model simulations as the residual from the rate of increase in atmospheric CO_2 and land and ocean CO_2 fluxes. Fluxes are accumulated over each 50-year period and converted to concentration units (ppm). Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

[END FIGURE 5.33 HERE]

5.6.2.1.3 Removal Effectiveness of CDR

It is well understood that land and ocean carbon fluxes are sensitive to the level of atmospheric CO_2 and climate change and differ under different future scenarios (Section 5.4). It is therefore important to establish to what extent the removal effectiveness of CDR – here defined as the fraction of total CO_2 removed remaining out of the atmosphere – is dependent on the scenario from which CDR is applied. Different metrics have been proposed to quantify the removal effectiveness of CDR (Tokarska and Zickfeld, 2015; Jones et al., 2016b; Zickfeld et al., 2016). One is the airborne fraction of cumulative CO_2 emissions (AF), defined in the same way as for positive emissions (i.e. as the fraction of total CO_2 emissions remaining in the atmosphere), with its use extended to periods of declining and net negative CO_2 emissions. This metric, however, has not proven to be useful to quantify the removal effectiveness of CDR in simulations where CDR is applied from a trajectory of increasing atmospheric CO_2 concentration, as it measures the carbon cycle response to CDR as well as to the prior atmospheric CO_2 trajectory (Tokarska and Zickfeld, 2015; Jones et al., 2016b). A more useful metric is the perturbation airborne fraction (PAF) (Jones et al., 2016b), which measures the airborne fraction of the perturbation (in this case the CO_2 removal) relative to a reference scenario (Tokarska and Zickfeld, 2015; Jones et al., 2016b). The advantage of this metric is that it isolates the response to a CO_2 removal from the response to atmospheric CO_2 prior to the point in time the removal is applied. A disadvantage is that the PAF cannot be calculated from a single model simulation but requires a reference simulation relative to which the effect of the CO_2 removal can be evaluated. When CDR is applied from an equilibrium state, the PAF and AF are equivalent measures.

In scenario simulations and idealised simulations with instantaneous CO_2 removals applied from an equilibrium state, the removal effectiveness of CDR is found to be slightly dependent on the rate and amount of CDR (Tokarska and Zickfeld, 2015; Jones et al., 2016b; Zickfeld et al., 2021), and to be strongly dependent on the emission scenario from which CDR is applied (Jones et al., 2016b; Zickfeld et al., 2021). The fraction of CO_2 removed remaining out of the atmosphere decreases slightly for larger removals and decreases strongly when CDR is applied from a lower background atmospheric CO_2 concentration (Figure

ACCEPTED VERSION SUBJECT TO FINAL EDITS

5.34), due to state dependencies and climate-carbon cycle feedbacks that lead to a stronger overall response to CO_2 removal (Zickfeld et al., 2021). Based on the *high agreement* between studies we assess with *medium confidence* that the removal effectiveness of CDR is only slightly dependent on the rate and magnitude of removal and is smaller at lower background atmospheric CO_2 concentrations. Simulations with Earth system models of EMIC with instantaneous CO_2 removal from different equilibrium initial states suggest that the smaller removal effectiveness of CDR at lower background CO_2 levels results in greater cooling per unit CO_2 removed (Zickfeld et al., 2021). However, there is *low confidence* in the robustness of this result as climate sensitivity has been shown to exhibit opposite state dependence in EMICs and ESMs (Section 7.4.3.1).

[START FIGURE 5.34 HERE]

Figure 5.34: Removal effectiveness of carbon dioxide removal (CDR). (a) Fraction of CO_2 remaining out of the atmosphere for idealised model simulations with CDR applied instantly (pulse removals) from climate states in equilibrium with different atmospheric CO_2 concentration levels (1 to 4 times the pre-industrial atmospheric CO_2 concentration; shown on the horizontal axis). The fraction is calculated 100 years after pulse removal. The black triangle and error bar indicate the multi-model mean and standard deviation for the seven Earth system models shown in Figure 5.32 forced with a 100 PgC pulse removal. Other symbols illustrate results with the UVic ESCM model of intermediate complexity for different magnitudes of pulse removals (triangles: –100 PgC; circles: –500 PgC; squares: –1000 PgC). Data for the UVic ESCM is from (Zickfeld et al., 2021). (b) Perturbation airborne fraction (see text for definition) for model simulations where CDR is applied from four RCPs (shown on the horizontal axis in terms of their cumulative CO_2 emissions during 2020–2099). Symbols indicate results for four CDR scenarios, which differ in terms of the magnitude and rate of CDR (see Jones et al. (2016b) for details). Results are based on simulations with the Hadley Centre Simple Climate-Carbon Model and are shown for the year 2100. Data from Jones et al. (2016b). Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

[END FIGURE 5.34 HERE]

5.6.2.1.4 Symmetry of Carbon Cycle Response to Positive and Negative CO_2 Emissions

It is commonly assumed that the climate-carbon cycle response to a negative CO_2 emission (i.e. removal from the atmosphere) is equal in magnitude and opposite in sign to the response to a positive CO_2 emission of equal magnitude, that is, symmetric. If the response were symmetric, a positive CO_2 emission could be offset by a negative emission. This subsection assesses the symmetry in the coupled climate-carbon cycle response in model simulations with positive and negative CO_2 emission pulses applied from a pre-industrial climate state. Simulations with seven CMIP6 ESMs and the UVic ESCM model of intermediate complexity suggest that the carbon cycle response is asymmetric for pulse emissions/removals of ±100 PgC (Figure 5.35). For all models, the fraction of CO_2 remaining in the atmosphere after an emission is larger than the fraction of CO_2 remaining out of the atmosphere after a removal (by 4 ± 3%; mean ± standard deviation). In other words, an emission of CO_2 into the atmosphere is more effective at raising atmospheric CO_2 than an equivalent CO_2 removal is at lowering it. Sensitivity experiments with the UVic ESCM suggest that the asymmetry increases for larger amounts of emissions/removals and is insensitive to the background atmospheric CO_2 concentration from which the emissions/removals are applied (Figure 5.35). This asymmetry in the atmospheric CO_2 response originates from asymmetries in the land and ocean carbon fluxes due to nonlinearities in the carbon cycle response to CO_2 and temperature (Section 5.4) (Zickfeld et al., 2021). Given *medium evidence* and *high agreement*, there is *medium confidence* in the sign of the asymmetry of the carbon cycle response to positive and negative CO_2 emissions. The sign of the symmetry of the temperature response, on the other hand, differs between models, with three out of seven examined ESMs showing a smaller temperature response to a 100 PgC CO_2 emission than to an equivalent CO_2 removal. Therefore, there is *low confidence* in the sign of the asymmetry of the temperature response to positive and negative CO_2 emissions.

ACCEPTED VERSION SUBJECT TO FINAL EDITS

[START FIGURE 5.35 HERE]

Figure 5.35: Asymmetry in the atmospheric carbon dioxide (CO_2) response to CO_2 emissions and removals. Shown are the fractions of total CO_2 emissions remaining in the atmosphere (right-hand side) and CO_2 removals remaining out of the atmosphere (left-hand side) 80–100 after a pulse emission/removal. Triangles and green circles denote results for seven Earth system models (ESMs) and the UVic ESCM model of intermediate complexity forced with ±100 PgC pulses applied from a pre-industrial state ($1\times CO_2$) (CDRMIP experiment CDR-pi-pulse; Keller et al. (2018b)). Yellow circles and diamonds indicate UVic ESCM results for CO_2 emissions/removals applied at 1.5 times ($1.5\times CO_2$) and 2 times ($2\times CO_2$) the pre-industrial CO_2 concentration, respectively. Pulses applied from a $2\times CO_2$ state span the magnitude ±100 PgC to ±500 PgC. UVic ESCM data is from (Zickfeld et al., 2021). Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

[END FIGURE 5.35 HERE]

5.6.2.2 Effects of Specific CDR Methods on Biogeochemical Cycles and Climate

WGI AR5 Chapter 6 discussed the CDR methods, their implications and unintended side effects on carbon cycle and climate, including their time scales and potentials. Since then, three IPCC special reports (SR) have been published. First, SR15 Chapter 4 (IPCC, 2018a) assessed the potentials and current understanding, including the side effects, of BECCS, afforestation/reforestation, soil carbon sequestration, biochar, enhanced weathering, ocean alkalinisation, DACCS and ocean fertilisation. Second, SRCCL Chapter 6 (IPCC, 2019a) assessed the potentials, co-benefits and trade-offs of land-based mitigation options. It assessed with *high confidence* that land-based CDR options do not sequester carbon indefinitely, except for peatland restoration. Multiple co-benefits were identified in the deployment of CDR options, many of them with a potential to make positive contributions to sustainable development, enhancement of ecosystem functions and services and other societal goals. However, their potential was concluded to be context specific and limits to their contribution to global mitigation, such as competition for land, were identified. The third report, SROCC Chapter 5 (IPCC, 2019b), assessed the potential of marine options for climate change mitigation. It concluded that the feasibility of open ocean fertilisation and alkalinisation approaches were negligible, due to their inconclusive influence on ocean carbon storage on long timescales, due to the unintended side effects on marine ecosystems, and the associated governance challenges. The assessment of the benefits of blue carbon ecosystems concluded that they could contribute only minimally to atmospheric CO_2 reduction globally but emphasised that the benefits of protection and restoration of coastal blue carbon extend beyond climate mitigation (SROCC Section 5.5.12).

5.6.2.2.1 Land-based Biological CDR Methods

Biological CDR methods, introduced in Table 5.9, seek to increase carbon storage on land by enhancing net primary productivity and/or reducing CO_2 sources to the atmosphere.

Forest-based methods include afforestation, reforestation, and forest management (Table 5.9). Building on previous work that emphasized the global potentials of various options, more recent advances have focused on the limits of those global potentials in light of ecological and climate risks that can threaten the long-term permanence of carbon stocks (Boysen et al., 2017b; Anderegg et al., 2020). Some of those risks arise from droughts, fires, insect outbreaks, diseases, erosion, and other disturbances (Thompson et al., 2009).

Sustainable forest management can help to manage some of these vulnerabilities, while in some cases, it can increase and maintain forest sinks through harvest, transfer of carbon to wood products and their use to store carbon and substitute emissions-intensive construction materials (Churkina et al., 2020). Forest genomics techniques can increase the success of both reforestation and conservation initiatives, accelerating breeding for tree health and productivity (Isabel et al., 2020).

In response to increasing risks to permanence of carbon stocks of some types of afforestation practices and the competition for land, there has been an increasing recognition that secondary forest regrowth and

ACCEPTED VERSION SUBJECT TO FINAL EDITS

restoration of degraded forests and non-forest ecosystems can play a large role in carbon sequestration (*high confidence*). The rational for this focus builds on their high carbon stocks and rates of sequestration (Griscom et al., 2017; Lewis et al., 2019; Maxwell et al., 2019; Pugh et al., 2019b), high resilience to disturbances (Dymond et al., 2014; Messier et al., 2019), and more additional benefits such as enhanced biodiversity (Strassburg et al., 2020).

The global sequestration potential of forestation varies substantially depending on the scenario-assumptions of available land and of background climate (WGIII AR6 Section 7.5). Afforestation of native grasslands, savannas, and open-canopy woodlands leads to the undesirable loss of unique natural ecosystems with rich biodiversity, carbon storage and other ecosystem services (Veldman et al., 2015; IBPES, 2018). Comprehensive approaches to assess the effectiveness of land-based carbon removal options need to be based on the whole carbon cycle covering both carbon stocks and flows, and establishing the links between human activities and their impacts on the biosphere and atmosphere (Keith et al., 2021).

A range of mechanisms could enhance CO_2 sequestration of forest-based methods under future scenarios, including CO_2 fertilisation, soil carbon enrichment due to enhanced litter input, or the northward shift of the tree-line in future climate projection (Bathiany et al., 2010; Sonntag et al., 2015; Boysen et al., 2017; Harper et al., 2018). There is *low confidence* in the net direction of feedbacks of afforestation on global mean temperature. The feedbacks are highly region dependent. For instances, afforestation at high latitudes would decrease albedo and increase local warming, while at low latitudes, the cooling effect of enhanced evapotranspiration could exceed the warming effect due to albedo decrease (Pearson et al. 2013; Zhang et al. 2013; Jia et al. 2019, SRCCL Section 2.6.1). Both afforestation and reforestation affect the hydrological cycle through increased VOC emissions and cloud albedo (Teuling et al., 2017; Kalliokoski et al., 2020), enhanced precipitation (Ellison et al., 2017) and increased transpiration, with potential effects on runoff and, especially in dry areas, on water supply (Farley et al., 2005; Smith et al., 2016; Krause et al., 2017; Teuling et al., 2019) (Figure 5.36, Cross-Chapter Box 5.1). Forest-based methods can either raise or lower N_2O emissions, depending on tree species, previous land use, soil type and climatic factors (*low confidence)* (Benanti et al., 2014; Chen et al., 2019; McDaniel et al., 2019) (Figure 5.36, Supplementary Materials, Table 5.SM.4) . Afforestation will decrease biodiversity if native species are replaced by monocultures (*high confidence)*, while there is *medium confidence* that biodiversity is improved when forests are introduced into land areas with degraded soils or intensive monocultures, or where native species are re-introduced into managed land (Hua et al., 2016; Williamson, P., & Bodle, 2016; Smith et al., 2018c; Holl and Brancalion, 2020) (Figure 5.36, Supplementary Materials Table 5.SM.4).

Soil carbon losses from human agriculture accounted for about 116 PgC in the last 12,000 years (Sanderman et al., 2017), (Section 5.2.1.2). With best management practices, two-thirds of these losses may be recoverable, setting a theoretical maximum of 77 PgC that can be sequestered in soils. Methods to increase soil carbon content may be applied to the restoration of marginal or degraded land (Paustian et al., 2016; Smith, 2016), but may also be used in traditional agricultural lands. A simple practice is to increase the input of carbon to the soil by selecting appropriate varieties or species with greater root mass (Kell, 2011) or higher yields and NPP (Burney et al., 2010). In addition, improved agricultural practices also increase soil carbon content. These include the use of crop rotation cycles, increase the amount of crop residues, use of crop cover to prevent periods of bare soil (Poeplau and Don, 2015; Griscom et al., 2017), optimisation of grazing (Henderson et al., 2015) and residue management (Wilhelm et al., 2004), use of irrigation (Campos et al., 2020), employment of low-tillage or no-tillage (Sun et al., 2020b), agroforestry, and cropland nutrient recycling, and avoid grassland conversion management (Paustian et al., 2016; Fargione et al., 2018). With *medium confidence,* methods which seek soil carbon sequestration will diminish N_2O emissions and nutrient leaching, and improve soil fertility and biological activity (Tonitto et al., 2006; Fornara et al., 2011; Paustian et al., 2016a; Smith et al., 2016; SRCCL 2.6.1.3, IPCC, 2019a; Figure 5.36). However, if improved soil carbon sequestration practices involve higher fertilisation rates, N_2O emissions would increase (Gu et al., 2017). Some soil carbon sequestration methods, such as cover crops and crop diversity, can increase biodiversity (*medium confidence*) (Paustian et al., 2016; Smith et al., 2018).

Biochar is produced by burning biomass at high temperatures under anoxic conditions (pyrolysis) and can, when added to soils, increase soil carbon stocks and fertility for decades to centuries (Woolf et al., 2010;

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Lehmann et al., 2015). Biochar application improves many soil qualities and increase crop yield (*medium confidence*) (Ye et al., 2020; SRCCL Chapter 4.9.5), particularly in already degraded or weathered soils (Woolf et al., 2010; Lorenz and Lal, 2014; Jeffery et al., 2016), increases soil water holding capacity (*medium confidence*) (Karhu et al., 2011; Liu et al., 2016; Fischer et al., 2019a; Verheijen et al., 2019) and evapotranspiration (*low confidence)* (Fischer et al., 2019). The use of biochar reduces nutrient losses (*low confidence*) (Woolf et al., 2010), enhances fertiliser nitrogen use efficiency and improves the bioavailability of phosphorus (Clough et al., 2013; Shen et al., 2016; Liu et al., 2017b; Figure 5.36). Biochar addition may decrease CH_4 emissions in inundated and acid soils such as rice fields (*low confidence*) (Jeffery et al., 2016; Huang et al., 2019; Wang et al., 2019a; Yang et al., 2019a). In non-inundated, neutral soils CH_4 uptake from the atmosphere is suppressed after biochar application (*low confidence*) (Jeffery et al., 2016), and soil N_2O emissions decline (*medium confidence*) (Cayuela et al., 2014; Kammann et al., 2017). Potential risks of introducing harmful contaminants into the soil environment are not well understood (Lorenz and Lal, 2014). With *low confidence*, application of biochar can have co-benefits for soil microbial biodiversity (Smith et al., 2018), while the potential trade-offs for biodiversity are due to land requirements (Tisserant and Cherubini, 2019).

Peatlands are less extensive than forests, croplands and grazing lands, yet per unit area, they hold high carbon stocks (Griscom et al., 2017). Peatland restoration relies on back-conversion or building of high-carbon-density soils through flooding, that is rewetting (Leifeld et al., 2019). High water level and anoxic conditions are prerequisites for restoring by returning drained and/or degraded peatlands back to their natural state as CO_2 sinks, but restoration also results in enhanced CH_4 emissions which are similar or higher than the pre-drainage fluxes (*high confidence)* (Koskinen et al., 2016; Wilson et al., 2016a; Hemes et al., 2019; Renou-Wilson et al., 2019; Holl et al., 2020). In a multi-decadal timeframe, the reduction in CO_2 emissions from rewetting more than compensates for the initial increase in radiative forcing due to enhanced CH_4 emissions (Günther et al., 2020). Rewetting drained peatlands will decrease N_2O emissions (*medium confidence*) (Wilson et al., 2016b; Liu et al., 2020a; Tiemeyer et al., 2020). Restored wetlands and peatlands act as buffer zones that provide infiltration and nutrient retention and offer protection to water quality (Daneshvar et al., 2017; Lundin et al., 2017), particularly in nutrient-loaded agricultural catchments. Peatland restoration can also recover much of the original biodiversity (*medium confidence*) (Meli et al., 2014; Smith et al. 2018).

The concept of bioenergy with carbon capture and storage (BECCS) rests on the premise that bioenergy production is carbon neutral, that is as much CO_2 is sequestered when growing biomass as feedstock as is released by its combustion. If these emissions are also captured and stored, the net effect is removal of CO_2 from the atmosphere (Fuss et al., 2018). Sequestration potentials from BECCS depend strongly on the feedstock, climate, and management practices (Beringer et al., 2011; Kato & Yamagata, 2014; Heck et al., 2016; Smith et al., 2016; Krause et al., 2017). If woody bioenergy plants replace marginal land, net carbon uptake increases, enriching soil carbon (Don et al., 2012; Heck et al., 2016; Boysen et al., 2017a,b). On the other hand, replacing carbon-rich ecosystems with herbaceous bioenergy plants could deplete soil-carbon stocks and reduce the additional sink capacity of standing forests (Don et al., 2012; Harper et al., 2018). Furthermore, wood-based BECCS may not be carbon negative in the first decades, initially emitting more CO_2 than sequestering (Sterman et al., 2018). BECCS has several trade-offs to deal with, including possible threats to water supply and soil nutrient deficiencies (*medium confidence*) (Smith et al., 2016; Krause et al., 2017; de Coninck et al., 2018; Heck et al., 2018; Roy et al., 2018) (SRCCL Chapters 2 and 6, Cross-Chapter Box 5.1). Deployment of BECCS at the scales envisioned by many 1.5–2.0°C mitigation scenarios could threaten biodiversity and require large land areas, competing with afforestation, reforestation and food security (Smith et al. 2018; Anderson and Peters 2016). Additional risks and side effects are related to geologic carbon storage (Fuss et al., 2018) (see also Section 5.6.2.2.4).

In conclusion, land-based CDR methods that rely on enhanced net biological uptake and storage of carbon, have a wide range of biogeochemical and biophysical side effects, which can directly or indirectly strengthen or weaken the climate mitigation effect of a given method, or affect water quality and quantity, food supply and biodiversity (Figure 5.36). With the exception of a weakening of ocean carbon sequestration, there is *low confidence* in the Earth system feedbacks of these methods. Most methods are associated with a range of biogeochemical and biophysical side effects and co-benefits and trade-offs, but these are often highly

ACCEPTED VERSION SUBJECT TO FINAL EDITS

dependent on local context, management regime, prior land use, and scale (*high confidence*). Highest co-benefits are obtained with methods that seek to restore natural ecosystems and improve soil carbon sequestration (Figure 5.36) while highest trade-off possibilities (symmetry with the highest cobenefits) offs occurs for re/afforestation with monocultures and BECCS, again with strong dependence on scale and context (*medium confidence*).

5.6.2.2.2 Ocean-based Biological CDR Methods

Both ocean biological and physical processes drive the CO_2 exchange between the ocean and atmosphere. However, the ocean physical processes that remove CO_2 from the atmosphere, such as large-scale circulation, cannot be feasibly altered, so ocean CDR methods focus on increasing the productivity of ocean ecosystems, and subsequent sequestration of carbon (GESAMP, 2019). There has been no change to the assessment of SROCC (Section 5.5.1): there is *low confidence* that nutrient addition to the open ocean, either through artificial ocean upwelling or iron fertilisation, could contribute to climate mitigation, due to its inconclusive effect on carbon sequestration and risks of adverse side effects on marine ecosystems (Figure 5.36; Table 5.9; Supplementary Materials Text 5.SM.3; Supplementary Materials Table 5.SM.4; WGIII, Section 12.3; Gattuso et al., 2018; Boyd and Vivian, 2019; Feng et al., 2020). In addition, ocean fertilisation is currently prohibited by the London Protocol (Dixon et al., 2014; GESAMP, 2019).

Restoration of vegetated coastal ecosystems (sometimes referred to as 'blue carbon' – see Glossary, Annex VII) refers to the potential for increasing carbon sequestration by plant growth and burial of organic carbon in the soil of coastal wetlands (including salt marshes and mangroves) and seagrass ecosystems. Wider usage of the term blue carbon occurs in the literature, for example including seaweeds (macroalgae), shelf sea sediments and open ocean carbon exchanges. However, such systems are less amenable to management, with many uncertainties relating to the permanence of their carbon stores (Windham-Myers et al., 2018; Lovelock and Duarte, 2019; SROCC Section 5.5.1.1).

Coastal wetlands and seagrass meadows store significant amounts of carbon and are among the most productive ecosystems per unit area (Griscom et al., 2017, 2020; Ortega et al., 2019; Serrano et al., 2019). These rates could be reduced in the future, since these habitats are vulnerable to changing conditions, such as temperature, salinity, sediment supply, storm severity and continued coastal development (National Academies of Sciences and Medicine, 2019; Bindoff et al., 2019). These ecosystems are under threat from anthropogenic conversion and degradation and are being lost at rates between 0.7% and 7% per annum with consequent CO_2 emissions (e.g. Atwood et al., 2017; Howard et al., 2017; Hamilton and Friess, 2018; Sasmito et al., 2019). Although sea level rise might lead to greater carbon sequestration in coastal wetlands (Rogers et al., 2019), there is *high confidence* that the frequency and intensity of marine heatwaves will increase (Cross-Chapter Box 9.1; Frölicher and Laufkötter, 2018; Laufkötter et al., 2020),which poses a more immediate threat to the integrity of coastal carbon stocks (Smale et al., 2019). Blue carbon restoration seeks to increase the rate of carbon sequestration, although restoration may be challenging, because of on-going use of coastal land for human settlement, conversion to agriculture and aquaculture, shoreline hardening and port development.

Biogeochemical factors affecting reliable quantification of the climatic benefits of coastal vegetation include the variable production of CH_4 and N_2O by such ecosystems (Adams et al., 2012; Rosentreter et al., 2018; Keller, 2019), uncertainties regarding the provenance of the carbon that they accumulate (Macreadie et al., 2019), and the release of CO_2 by biogenic carbonate formation in seagrass ecosystems (Kennedy et al., 2018). Whilst coastal habitat restoration potentially provides significant mitigation of national emissions for some countries (Taillardat et al., 2018; Serrano et al., 2019), the global sequestration potential of blue carbon approaches is <0.02 PgC yr^{-1} (*medium confidence*) (Figure 5.36; SROCC Section 5.5.1.2; Griscom et al., 2017; Gattuso et al., 2018; National Academies of Sciences and Medicine, 2019).

5.6.2.2.3 Geochemical CDR Methods

Enhanced weathering (EW) is based on naturally occurring weathering processes of silicate and carbonate rocks, removing CO_2 from the atmosphere. Weathering is accelerated by spreading ground rocks on soils,

ACCEPTED VERSION SUBJECT TO FINAL EDITS

coasts or oceans. EW increases the alkalinity and pH of natural waters, helps dampen ocean acidification and increases ocean carbon uptake (Beerling et al., 2018). The dissolution of minerals stimulates biological productivity of croplands (Hartmann et al., 2013; Beerling et al., 2018), but can also liberate toxic trace metals (such as Ni, Cr, Cu) into soil or water bodies (Keller et al. 2018; Strefler et al. 2018). EW can also contribute to freshwater salinisation as a result of increased salt inputs and cation exchange in watersheds, and so adversely affecting drinking water quality (*low confidence*) (Kaushal et al., 2018). With a *medium confidence*, amendment of soils with minerals will have lower N_2O emissions (Blanc-Betes et al.; Kantola et al., 2017) but will not have a marked effect on evapotranspiration or albedo (Fuss et al., 2018; de Oliveira Garcia et al., 2020). The mining of minerals can cause adverse impacts on biodiversity, however the use of waste materials such as concrete demolition or steel slags for EW can reduce the need for mining (Renforth, 2019). The spreading of minerals on land has a neutral impact on biodiversity (Smith et al. 2018)

Ocean alkalinisation, via the deposition of alkaline minerals (e.g. olivine) or their dissociation products (e.g. quicklime) at the ocean surface, can increase surface total alkalinity and thus increase CO_2 uptake and storage (see Glossary, Annex VII; Supplementary Material Text 5.SM.3; WGIII Section 12.3; GESAMP 2019; Keller 2019). Ocean alkalinisation ameliorates somewhat surface ocean acidification (*high confidence*; Hauck et al., 2016; Tran et al., 2020), there are also negative side effects on the marine ecosystem, most of which are poorly understood or quantified (Bach et al., 2019; Figure 5.36; Supplementary Materials Table 5.SM.4). Although ocean alkalinisation could potentially sequester large amounts of carbon ($\geq$1 PgC yr^{-1}; Figure 5.36; Supplementary Materials Table 5.SM.5) there is no new evidence to revisit the SROCC (Section 5.5.1.2.4) conclusion that there is *low confidence* that ocean alkalinisation is a viable climate mitigation approach.

5.6.2.2.4 Chemical CDR methods

Direct air carbon capture with carbon storage (DACCS) is a combination of two techniques, direct capture of CO_2 from ambient air (DAC) and carbon storage. DAC entails contacting the air, capturing the CO_2 on a liquid solvent or solid sorbent, and regenerating the solvent or sorbent. Different DAC methods have been proposed, which differ by the chemical process used to capture the CO_2 and to recover it from the sorbent or solvent (NASEM, 2019). The captured CO_2 may be either stored geologically as a high-pressure gas or sequestered by a mineral carbonation process. Storage is potentially permanent in both pressurised gas and mineral form (Fuss et al., 2018). DACCS has significant requirements of energy and, depending on the type of technology, water and materials (Smith et al., 2016; NASEM, 2019). Compared to other CDR methods it has a small land footprint (Smith et al., 2016; NASEM, 2019). Side effects of DACCS include CO_2-depleted air leaving the air contactor, which could have adverse effects on crop and ecosystem productivity, and VOC emissions (NASEM, 2019). Additional risks and side effects are related to the high pressure at which CO_2 is stored in geologic formations (Fuss et al., 2018). DACCS is assessed in detail in WGIII Section 12.3.

5.6.2.2.5 Methane removal

Proposals to remove CH_4 from the atmosphere are emerging (de Richter et al., 2017; Jackson et al., 2019). CH_4 removal methods seek to capture CH_4 directly from ambient air similarly to DACCS for CO_2 using for example zeolite trapping, but instead of storing it CH_4 would be chemically oxidized to CO_2 (Jackson et al., 2019). Methane can be also removed microbially by supporting naturally occurring processes, for example by enhancing the soil microbial uptake through afforestation (Wu et al., 2018b) or by directing the venting air from a cow barn into the soil bed of a nearby greenhouse, utilising microbial CH_4 oxidation (Nisbet et al., 2020). Microbial CH_4 oxidation could also be utilized for removal of CH_4 leaked from point sources by building biocatalytic polymers which include methane-oxidizing enzymes (Blanchette et al., 2016). Methane removal is, however, still in its infancy and the available literature is insufficient for an assessment.

[START FIGURE 5.36 HERE]

Figure 5.36: Characteristics of carbon dioxide removal (CDR) methods, ordered according to the time scale of carbon storage. The first column shows biogeophysical (for open-ocean methods) or technical (for all

ACCEPTED VERSION SUBJECT TO FINAL EDITS

other methods) sequestration potentials (i.e. the sequestration potentials constrained by biological, geophysical, geochemical limits and thermodynamics and, for technical potentials, availability of technologies and practices; technical potentials for some methods also consider social or environmental factors if these represent strong barriers for deployment; see Glossary, Annex VII), classified into low (< 0.3 $GtCO_2$ yr^{-1}), moderate (0.3−3 $GtCO_2$ yr^{-1}) and large (>3 $GtCO_2$ yr^{-1}) (details underlying this classification are provided in Supplementary Materials Table 5.SM.5). The other columns show Earth system feedbacks that deployment of a given CDR method would have on carbon sequestration and climate, along with biogeochemical, biophysical, and other side effects of a given method. Earth system feedbacks do not include the direct effect of CO_2 sequestration on atmospheric CO_2, only secondary effects. For Earth system feedbacks, the colours indicate whether the feedbacks strengthen or weaken carbon sequestration and the climate cooling effect of a given CDR method. For biogeochemical and biophysical side effects the colours indicate whether the deployment of a CDR method increases or decreases the magnitude of the effect, whereas for co-benefits and trade-offs the colour indicates whether deployment of a CDR method results in beneficial (co-benefits) or adverse side-effects (trade-offs) for water quality and quantity, food production and biodiversity. The details and references underlying the Earth system feedback and side-effect assessment are provided in Supplementary Materials Table 5.SM.4. Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

[END FIGURE 5.36 HERE]

5.6.3 Biogeochemical responses to Solar Radiation Modification (SRM)

This section assesses the possible consequences of solar radiation modification (SRM) on the biosphere and global biogeochemical cycles. The SRM options (Table 4.6) and the physical climate response to SRM is assessed in detail in Chapter 4 (Section 4.6.3). Chapter 6 (Section 6.3.6) assesses the potential effective radiative forcing of aerosol-based SRM options and Chapter 8 (Section 8.6.3) assesses the abrupt water cycle changes in response to initiation or termination of SRM. Most literature on the biogeochemical responses to SRM focuses on stratospheric aerosol injection (SAI), and only a few studies have investigated the biogeochemical responses to marine cloud brightening (MCB) and cirrus cloud thinning (CCT). At the time of AR5, there were only a few studies on the biogeochemical responses to SRM. The main assessment of AR5 (Ciais et al., 2013) was that SRM will not interfere with the direct biogeochemical effects of increased CO_2 such as ocean acidification and CO_2 fertilisation effect but could affect the carbon cycle through climate-carbon feedbacks. Overall, AR5 concluded that the level of confidence on the effects of SRM on carbon and other biogeochemical cycles is *very low* (Ciais et al., 2013). Since AR5, more modelling work has been conducted to examine various aspects of the global biogeochemical cycle responses to SRM.

5.6.3.1 Effects of SRM on the Carbon Cycle

Relative to a high-GHG world without SRM, SRM would affect the carbon cycles through changes in sunlight, climate (e.g. temperature, precipitation, soil moisture, ocean circulation), and atmospheric chemistry (e.g. ozone) (Cao, 2018) (Section 4.6.3.3). Net SRM effects on the carbon cycle, relative to a world without SRM, depend on the change of individual factors, and interactions among them.

SRM-mediated sunlight changes directly affect the carbon cycle. In particular, SAI would reduce the sunlight reaching the Earth's surface, but also increase the fraction of sunlight that is diffuse. These changes in the quantity and quality of the sunlight have opposing effects on the photosynthesis of land plants. On their own, reductions in photosynthetically active radiation (PAR) will reduce photosynthesis. However, diffuse light is more effective than direct light in accessing the light-limited leaves within plant canopies, leading to the so-called 'diffuse-radiation' fertilisation effect (Mercado et al., 2009). The estimated balance between the negative impacts of reducing PAR and the positive impacts of increasing diffuse fraction differ between models (Kalidindi et al., 2015; Xia et al., 2016; Yang et al., 2020a) and across different ecosystems. The change in the absolute amount of direct and diffuse radiation could also depend on the height of the additional sulphate aerosol layer in the stratosphere and the hygroscopic growth of aerosols (Krishnamohan et al., 2019, 2020) .

ACCEPTED VERSION SUBJECT TO FINAL EDITS

SRM-mediated cooling also affects the terrestrial carbon cycle. Relative to a high-GHG world without SRM, the simulated responses of net primary production (NPP) to SRM differ widely between models, such that even the sign of global mean change is uncertain (Glienke et al., 2015). SRM-induced cooling would decrease NPP at high latitudes by reducing the length of the growing season (Glienke et al., 2015). At low latitudes, the NPP response to SRM-induced cooling is sensitive to the effect of nitrogen limitation (Duan et al., 2020; Glienke et al., 2015;). SRM-induced cooling tends to increase NPP in models without the nitrogen cycle because of reduced heat stress. However, in models including the nitrogen cycle, this is counteracted by reductions in NPP because of reductions in nitrogen mineralisation and nitrogen availability (Glienke et al., 2015). SRM-induced changes in the hydrological cycle (Section 8.6.3), including changes in evapotranspiration, precipitation, and soil moisture, also pose strong constraints on the vegetation response (Dagon and Schrag, 2019). For the same amount of global mean cooling, different SRM options, such as SAI, MCB, and CCT, would have different effects on GPP and NPP because of different spatial patterns of temperature available sunlight, and hydrological cycle changes (Section 4.6.3.3) (Duan et al., 2020). Modelling studies show that SRM-induced cooling would reduce plant and soil respiration (Tjiputra et al., 2016; Cao and Jiang, 2017; Muri et al., 2018; Yang et al., 2020b). Thus, despite the large uncertainty in modelled NPP response, existing modelling studies consistently show that relative to a high-CO_2 world without SRM, SRM would increase the global land carbon sink (*high confidence*).

Based on available evidence, SRM with elevated CO_2 would increase global mean NPP and carbon storage on land, relative to an unperturbed climate mainly because of CO_2 fertilisation of photosynthesis (Glienke et al., 2015; Tjiputra et al., 2016; Dagon and Schrag, 2019; Duan et al., 2020; Yang et al., 2020b) (*high confidence*). However, the amount of increase is uncertain as it depends on the extent to which CO_2 fertilisation of land plants is limited by nutrient availability.

[START FIGURE 5.37 HERE]

Figure 5.37: Cumulative carbon dioxide (CO_2) uptake by land and ocean carbon sinks in response to stratospheric sulfur dioxide (SO_2) injection. Results are shown for a scenario with 50-year (2020−2069) continuous stratospheric SO_2 injection at a rate of 5 Tg per year appplied to a RCP4.5 baseline scenario (GeoMIP experiment G4; Kravitz et al., (2011)), followed by termination in year 2070. Anomalies are shown relative to RCP4.5 for the multimodel ensemble mean and for each of six ESMs over the 50-year period of stratospheric SO_2 injection (left), and over 20 years after termination of SO_2 injection (right). Adapted from Plazzotta et al. (2019). Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

[END FIGURE 5.37 HERE]

Relative to a high-CO_2 world without SRM, SRM would also have compensating effects on crop yields. SRM is expected to have a positive impact on crop yields by diminishing heat stress (Pongratz et al., 2012). However, reductions in light availability will produce a counteracting reduction in crop yields, especially if the crop type does not benefit appreciably from diffuse-light fertilisation (Proctor et al., 2018). The balance between these effects varies markedly across crop types and regions, from projected increases in maize production in China (Xia et al., 2014) to reductions in groundnut yields in parts of India (Yang et al., 2016). Because of these diverging results from a limited set of studies, there is overall *low confidence* in the effect of SRM on crop yields.

Consistent with the AR5 assessment, there is *high confidence* that SRM would not mitigate CO_2-induced ocean acidification (Ciais et al., 2013). Some studies even suggest an acceleration of deep-ocean acidification as a result of ocean circulation change (Tjiputra et al., 2016; Lauvset et al., 2017). There are large differences in the simulated spatial pattern of ocean NPP change in response to SRM, which depends strongly on the SRM method that is considered (Partanen et al., 2016; Lauvset et al., 2017).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

5.6.3.2 Consequences of SRM and its termination on atmospheric CO2 burden

Modelling studies consistently show that relative to a high-CO_2 world without SRM, SRM-induced cooling (Section 4.6.3.3) would reduce plant and soil respiration, and also reduce the negative effects of warming on ocean carbon uptake (Tjiputra et al., 2016; Xia et al., 2016; Cao and Jiang, 2017; Jiang et al., 2018; Muri et al., 2018; Sonntag et al., 2018; Plazzotta et al., 2019; Yang et al., 2020b). A multi-model study (Plazzotta et al., 2019) indicates that relative to a high-CO_2 concentration world without SRM, statospheric SO_2 injection increases the allowable CO_2 emission by enhancing CO_2 uptake by both land and ocean (Figure 5.37). As a result of enhanced global carbon uptake, SRM would reduce the burden of atmospheric CO_2 (*high confidence*). However, the amount of SRM-induced reduction in atmospheric CO_2 depends on the future emission scenario and modelled oceanic and terrestrial carbon sinks, which differ widely between models (Tjiputra et al., 2016; Xia et al., 2016; Cao and Jiang, 2017; Muri et al., 2018). Models that include the terrestrial nitrogen cycle usually report a much smaller reduction of atmospheric CO_2 in response to SRM than models without the nitrogen cycle mainly because nitrogen limitation leads to a weaker terrestrial carbon sink (Tjiputra et al., 2016; Muri et al., 2018; Yang et al., 2020b). Large scale application of SAI is found to reduce the rate of release of CO_2 and CH_4 from permafrost thaw (Lee et al., 2019; Chen et al., 2020).

A hypothetical, sudden and sustained termination of SRM would cause a rapid increase in global warming that poses great risks to biodiversity (Jones et al., 2013a; McCusker et al., 2014; Trisos et al., 2018) (Section 4.6.3.3). A sudden and sustained termination of SRM would also weaken carbon sinks, accelerating atmospheric CO_2 accumulation and inducing further warming (Figure 5.37) (Matthews and Caldeira, 2007; Tjiputra et al., 2016; Muri et al., 2018; Plazzotta et al., 2019). However, a scenario with gradual phase-out of SRM under emission reduction could reduce the large negative effect of sudden SRM termination (MacMartin et al., 2014; Keith and MacMartin, 2015; Tilmes et al., 2016), though this would be limited by how rapidly emission reductions can be scaled-up (Ekholm and Korhonen, 2016).

5.6.3.3 Consequences of SRM on other Biogeochemical Cycles

SAI is found to reduce global average surface ozone concentration (Xia et al., 2017) mainly as a result of aerosol-induced reduction in stratospheric ozone at polar regions, resulting in reduced transport of ozone from the stratosphere (Pitari et al., 2014; Tilmes et al., 2018). The reduction in surface ozone, together with alteration to UV radiation, would have important implications for vegetation response (Xia et al., 2017). A modelling study shows that sea salt aerosol injection for MCB would reduce OH concentration and increase CH_4 lifetime, and hence, have potential implications for surface ozone pollution (Horowitz et al., 2020). It has also been reported that the use of SAI to limit global mean warming from 2°C to 1.5°C would reduce fire weather in many areas (Burton et al., 2018).

5.6.3.4 Synthesis of biogeochemical responses to SRM

SRM would alter the global carbon cycle through SRM-induced climate effect such as changes in sunlight, temperature, precipitation, and ocean circulation. Compared to high-CO_2 world without SRM, SRM would enhance the net uptake of CO_2 by the terrestrial biosphere and ocean, thus acting to reduce atmospheric CO_2 (*high confidence*). SRM would also affect surface ozone, UV radiation, and atmospheric chemistry. Due to complex interplays between SRM-induced changes in direct and diffuse sunlight, temperature, the coupling of water-carbon-nitrogen cycles, and atmospheric chemistry, there is large uncertainty in the overall response of the terrestrial biosphere response to SRM. Thus, the level of *confidence* on the effect of SRM on carbon and other biogeochemical cycles is *low*.

5.7 Final Remarks

Key research developments to further strengthen the confidence levels in AR7.

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Contemporary Greenhouse Gases Trends and Attribution

- Further constrain the CO_2, CH_4 and N_2O fluxes from land use, land use change and forestry (including gross fluxes), and fossil fuels. Improving spatial resolution and representations of land management, such as forestry, grazing and cropping.
- Improve representation of the variability and trends in the transport of carbon through the land to ocean continuum, which has implications for partitioning of the land and ocean CO_2 sinks.
- Improve understanding of the controls over the airborne franction and sinks rates, their trends, and future dynamics.
- Fill gaps in space and time for ocean CO_2 and ancillary physical and biogeochemical observations at the ocean surface and interior to reduce the biases and uncertainties in the variability and trends for air-sea fluxes and inventory changes, particularly for the Arctic and the Southern Ocean.
- Reduce uncertainties in wetland CH_4 emissions, which is largest source term in the global CH_4 budget and proportionally have the largest uncertainty, in order to better understand future CH_4-climate feedbacks.
- Reduce uncertainties in atmospheric transport models used to estimate regional sources and sinks of greenhouse gases as independent evidence from that of ground and inventory estimates.

Ocean Acidification and Deoxygenation

- Improve observations for the interplay between carbonate chemistry and a variety of biogeochemical and physical processes including eutrophication and freshwater inflow in coastal zones to increase the robustness of future assessments of ocean acidification.
- Improve our understanding of changes in water mass ventilation associated with climate change and variability to gain further insights into future trends in ocean acidification and deoxygenation in the ocean interior.

Biogeochemical Feedbacks on Climate Change

- Improve understanding and representation in Earth system models (ESMs) of changes in land carbon storage and associated carbon-climate feedbacks including better treatment of the CO_2 fertilisation, nutrient-limitations, soil organic matter stabilisation and turnover; land use change; large-scale and fine-scale permafrost carbon; plant growth, mortality, and competition dynamics; plant hydraulics; and disturbance processes.
- Improve observations and process understanding of CH_4 and N_2O source responses to climate, specifically from wetlands and permafrost thaw.
- Improve observations and process understanding of ocean N_2O source responses to oxygen loss and climate particularly in the oxygen minimum zones of the tropical oceans and eastern boundary upwelling regions.
- Improve understanding of the sensitivity of ocean carbon-climate feedbacks to physical processes that are not yet resolved by the ocean domain in ESMs.
- Improve understanding of the processes affecting the efficiency, climate sensitivity and emerging feedbacks in the ocean carbon cycle via the biological carbon pump to constrain future global ocean feedbacks.

Remaining Carbon Budget to Climate Stabilisation

- Improve understanding of both the sign and magnitude of a possible zero emissions commitment (ZEC). The ZEC affects estimates of carbon budgets derived from the TCRE, but not TCRE itself. ZEC is particularly relevant once global CO_2 emissions decline towards net zero.
- Better constrain of the airborne fraction to reduce the spread in TCRE assessment.
- Accounting for timescales of Earth system feedbacks over time for increased accuracy of mitigation needs once global CO_2 emissions reach near-zero levels.

Carbon Dioxide Removal (CDR) and Solar Radiation Modification

- Run large-scale and long-term experiments and assessments to explore regional feasibility of CDR methods, that they present an actual and verifiable negative regional carbon balance, and that they do not result in adverse unintended consequences.

ACCEPTED VERSION SUBJECT TO FINAL EDITS

- Improve understanding of the effectiveness of CDR methods to lower atmospheric CO_2 and reduce warming taking into account Earth system feedbacks.

Frequently Asked Questions

FAQ 5.1: Is the natural removal of carbon from the atmosphere weakening?

For decades, about half of the carbon dioxide (CO_2) that human activities have emitted to the atmosphere has been taken up by natural carbon sinks in vegetation, soils and oceans. These natural sinks of CO_2 have thus roughly halved the rate at which atmospheric CO_2 concentrations have increased, and therefore slowed down global warming. However, observations show that the processes underlying this uptake are beginning to respond to increasing CO_2 in the atmosphere and climate change in a way that will weaken nature's capacity to take up CO_2 in the future. Understanding of the magnitude of this change is essential for projecting how the climate system will respond to future emissions and emission reduction-efforts.

Direct observations of CO_2 concentrations in the atmosphere, which began in 1958, show that the atmosphere has only retained roughly half of the CO_2 emitted by human activities due to the combustion of fossil fuels and land-use change such as deforestation (FAQ 5.1, Figure 1). Natural carbon cycle processes on land and in the oceans have taken up the remainder of these emissions. These land and ocean removals or 'sinks' have grown largely in proportion to the increase in CO_2 emissions, taking up 31% (land) and 23% (ocean) of the emissions in 2010–2019, respectively (FAQ 5.1, Figure 1). Therefore, the average proportion of yearly CO_2 emissions staying in the atmosphere has remained roughly stable at 44 % over the last six decades despite continuously increasing CO_2 emissions from human activities.

On land, it is mainly the vegetation that captures CO_2 from the atmosphere through *plant photosynthesis,* which ultimately accumulates both in vegetation and soils. As more CO_2 accumulates in the atmosphere, plant carbon capture increases through the so-called *CO_2 fertilisation effect* in regions where plant growth is not limited by, for instance, nutrient availability. Climate change affects the processes responsible for the uptake and release of CO_2 on land in multiple ways. Land CO_2 uptake is generally increased by longer growing seasons due to global warming in cold regions and by nitrogen deposition in nitrogen-limited regions. Respiration by plants and soil organisms, natural disturbances such as fires, and human activities such as deforestation all release CO_2 back into the atmosphere. The combined effect of climate change on these processes is to weaken the future land sink. In particular, extreme temperatures and droughts as well as permafrost thaw (see FAQ 5.2) tend to reduce the land sink regionally.

In the ocean, several factors control how much CO_2 is captured: the difference in CO_2 partial pressure between the atmosphere and the surface ocean; wind speeds at the ocean surface; the chemical composition of seawater (that is, its *buffering capacity*), which affects how much CO_2 can be taken up; and the use of CO_2 in photosynthesis by seawater microalgae. The CO_2-enriched surface ocean water is transported to the deep ocean in specific zones around the globe (such as the Northern Atlantic and the Southern Ocean), effectively storing the CO_2 away from the atmosphere for many decades to centuries. The combined effect of warmer surface ocean temperatures on these processes is to weaken the future ocean CO_2 sink.

The ocean carbon sink is better quantified than the land sink thanks to direct ocean and atmospheric carbon observations. The land carbon sink is more challenging to monitor globally, because it varies widely even regionally. There is currently no direct evidence that the natural sinks are slowing down, because observable changes in the fraction of human emissions stored on land or in oceans are small compared to year-to-year and decadal variations of these sinks. Nevertheless, it is becoming more obvious that atmospheric and climate changes are affecting the processes controlling the land and ocean sinks.

Since both the land and ocean sinks respond to the rise in atmospheric CO_2 and to human-induced global warming, the absolute amount of CO_2 taken up by land and ocean will be affected by future CO_2 emissions. This also implies that if countries manage to strongly reduce global CO_2 emissions, or even remove CO_2 from the atmosphere, these sinks will take up less CO_2 because of the reduced human perturbation of the carbon cycle. Under future high-warming scenarios, it is expected that the global ocean and land sinks will stop growing in the second half of the century as climate change increasingly affects them. Thus, both the total amount of CO_2 emitted to the atmosphere and the responses of the natural CO_2 sinks will determine what efforts are required to limit global warming to a certain level (see FAQ 5.4), underscoring how

ACCEPTED VERSION SUBJECT TO FINAL EDITS

important it is to understand the evolution of these natural CO_2 sinks.

FAQ 5.2: Can thawing permafrost substantially increase global warming?

In the Arctic, large amounts of organic carbon are stored in permafrost – ground that remains frozen throughout the year. If significant areas of permafrost thaw as the climate warms, some of that carbon may be released into the atmosphere in the form of carbon dioxide or methane, resulting in additional warming. Projections from models of permafrost ecosystems suggest that future permafrost thaw will lead to some additional warming – enough to be important, but not enough to lead to a 'runaway warming' situation, where permafrost thaw leads to a dramatic, self-reinforcing acceleration of global warming.

The Arctic is the biggest climate-sensitive carbon pool on Earth, storing twice as much carbon in its frozen soils, or *permafrost*, than is currently stored in the atmosphere. As the Arctic region warms faster than anywhere else on earth, there are concerns that this warming could release greenhouse gases to the atmosphere and therefore significantly amplify climate change.

The carbon in the permafrost has built up over thousands of years, as dead plants have been buried and accumulated within layers of frozen soil, where the cold prevents the organic material from decomposing. As the Arctic warms and soils thaw, the organic matter in these soils begins to decompose rapidly and return to the atmosphere as either carbon dioxide or methane, which are both important greenhouse gases. Permafrost can also thaw abruptly in a given place, due to melting ice in the ground reshaping Arctic landscapes, lakes growing and draining, and fires burning away insulating surface soil layers. Thawing of permafrost carbon has already been observed in the Arctic, and climate models project that much of the shallow permafrost (<3 m depth) throughout the Arctic would thaw under moderate to high amounts of global warming (2°C–4°C).

While permafrost processes are complex, they are beginning to be included in models that represent the interactions between the climate and the carbon cycle. The projections from these permafrost carbon models show a wide range in the estimated strength of a carbon–climate vicious circle, from both carbon dioxide and methane, equivalent to 14–175 billion tonnes of carbon dioxide released per 1°C of global warming. By comparison, in 2019, human activities have released about 40 billion tonnes of carbon dioxide into the atmosphere. This has two implications. First, the extra warming caused by permafrost thawing is strong enough that it must be considered when estimating the total amount of remaining emissions permitted to stabilise the climate at a given level of global warming (i.e., the remaining carbon budget, see FAQ 5.4). Second, the models do not identify any one amount of warming at which permafrost thaw becomes a 'tipping point' or threshold in the climate system that would lead to a runaway global warming. However, models do project that emissions would continuously increase with warming, and that this trend could last for hundreds of years.

Permafrost can also be found in other cold places (e.g., mountain ranges), but those places contain much less carbon than in the Arctic. For instance, the Tibetan plateau contains about 3% as much carbon as is stored in the Arctic. There is also concern about carbon frozen in shallow ocean sediments. These deposits are known as *methane hydrates* or *clathrates*, which are methane molecules locked within a cage of ice molecules. They formed as frozen soils that were flooded when sea levels rose after the last ice age. If these hydrates thaw, they may release methane that can bubble up to the surface. The total amount of carbon in permafrost-associated methane hydrates is much less than the carbon in permafrost soils. Global warming takes millennia to penetrate into the sediments beneath the ocean, which is why these hydrates are still responding to the last deglaciation. As a result, only a small fraction of the existing hydrates could be destabilised during the coming century. Even when methane is released from hydrates, most of it is expected to be consumed and oxidised into carbon dioxide in the ocean before reaching the atmosphere. The most complete modelling of these processes to date suggests a release to the atmosphere at a rate of less than 2% of current human-induced methane emissions.

Overall, thawing permafrost in the Arctic appears to be an important additional source of heat-trapping gases to the atmosphere, more so than undersea hydrates. Climate and carbon cycle models are beginning to consider permafrost processes. While these models disagree on the exact amount of the heat-trapping gases that will be released into the atmosphere, they agree (i) that the amount of such gases released from

ACCEPTED VERSION SUBJECT TO FINAL EDITS

permafrost will increase with the amount of global warming, and (ii) that the warming effect of thawing permafrost is significant enough to be considered in estimates of the remaining carbon budgets for limiting future warming.

FAQ 5.3: Could climate change be reversed by removing carbon dioxide from the atmosphere?

Deliberate removal of carbon dioxide (CO_2) from the atmosphere could reverse (i.e. change the direction of) some aspects of climate change. However, this will only happen if it results in a net reduction in the total amount of CO_2 in the atmosphere, that is, if deliberate removals are larger than emissions. Some climate change trends, such as the increase in global surface temperature, would start to reverse within a few years. Other aspects of climate change would take decades (e.g., permafrost thawing) or centuries (e.g., acidification of the deep ocean) to reverse, and some, such as sea level rise, would take centuries to millennia to change direction.

The term *negative carbon dioxide (CO_2) emissions* refers to the removal of CO_2 from the atmosphere by deliberate human activities, in addition to the removals that occur naturally, and is often used as synonymous with *carbon dioxide removal*. Negative CO_2 emissions can compensate for the release of CO_2 into the atmosphere by human activities. They could be achieved by strengthening natural CO_2 sequestration processes on land (e.g., by planting trees or through agricultural practices that increase the carbon content of soils) and/or in the ocean (e.g., by restoration of coastal ecosystems) or by removing CO_2 directly from the atmosphere. If CO_2 removals are greater than human-caused CO_2 emissions globally, emissions are said to be *net negative*. It should be noted that CO_2 removal technologies are not yet ready or unable to achieve the scale of removal that would be required to compensate for current levels of emissions, and most have undesired side effects.

In the absence of deliberate CO_2 removal, the CO_2 concentration in the atmosphere (a measure of the amount of CO_2 in the atmosphere) results from a balance between human-caused CO_2 release and the removal of CO_2 by natural processes on land and in the ocean (natural 'carbon sinks') (see FAQ 5.1). If CO_2 release exceeds removal by carbon sinks, the CO_2 concentration in the atmosphere would increase; if CO_2 release equals removal, the atmospheric CO_2 concentration would stabilise; and if CO_2 removal exceeds release, the CO_2 concentration would decline. This applies in the same way to *net* CO_2 emissions that is, the sum of human-caused releases and deliberate removals.

If the CO_2 concentration in the atmosphere starts to go down, the Earth's climate would respond to this change (FAQ 5.3, Figure 1). Some parts of the climate system take time to react to a change in CO_2 concentration, so a decline in atmospheric CO_2 as a result of net negative emissions would not lead to immediate reversal of all climate change trends. Recent studies have shown that global surface temperature starts to decline within a few years following a decline in atmospheric CO_2, although the decline would not be detectable for decades due to natural climate variability (see FAQ 4.2). Other consequences of human-induced climate change such as reduction in permafrost area would take decades, and yet others such as warming, acidification and oxygen loss of the deep ocean would take centuries to reverse following a decline in the atmospheric CO_2 concentration. Sea level would continue to rise for many centuries to millennia, even if large deliberate CO_2 removals were successfully implemented.

A class of future scenarios that is receiving increasing attention, particularly in the context of ambitious climate goals such as the global warming limits of 1.5°C or 2°C included in the Paris Agreement, are so-called 'overshoot' scenarios. In these scenarios, a slow rate of reductions in emissions in the near term is compensated by net negative CO_2 emissions in the later part of this century, which results in a temporary breach or 'overshoot' of a given warming level. Due to the delayed reaction of several climate system components, it follows that the temporary overshoot would result in additional climate changes compared to a scenario that reaches the goal without overshoot. These changes would take decades to many centuries to reverse, with the reversal taking longer for scenarios with larger overshoot.

Removing more CO_2 from the atmosphere than is emitted into it would indeed begin to reverse some aspects of climate change, but some changes would still continue in their current direction for decades to millennia. Approaches capable of large-scale removal of CO_2 are still in the state of research and development or unproven at the scales of deployment necessary to achieve a net reduction in atmospheric CO_2 levels. CO_2 removal approaches, particularly those deployed on land, can have undesired side-effects on water, food production and biodiversity.

[START FAQ 5.3, FIGURE 1 HERE]

FAQ 5.3, Figure 1: Changes in aspects of climate change in response to a peak and decline in the atmospheric CO_2 concentration (top panel). The vertical grey dashed line indicates the time of peak CO_2 concentration in all panels. It is shown that the reversal of global surface warming lags the decrease in the atmospheric CO_2 concentration by a few years, the reversal of permafrost area decline lags the decrease in atmospheric CO_2 by decades, and ocean thermal expansion continues for several centuries. Note that the quantitative information in the figure (i.e., numbers on vertical axes) is not to be emphasized as it results from simulations with just one model and will be different for other models. The qualitative behaviour, however, can be expected to be largely model independent.

FAQ 5.4: What are carbon budgets?

There are several types of carbon budgets. Most often, the term refers to the total net amount of carbon dioxide (CO_2) that can still be emitted by human activities while limiting global warming to a specified level (e.g., 1.5ºC or 2ºC above pre-industrial levels). This is referred to as the 'remaining carbon budget'. Several choices and value judgments have to be made before it can be unambiguously estimated. When the remaining carbon budget is combined with all past CO_2 emissions to date, a 'total carbon budget' compatible with a specific global warming limit can also be defined. A third type of carbon budget is the 'historical carbon budget', which is a scientific way to describe all past and present sources and sinks of CO_2.

The term *remaining carbon budget* is used to describe the total net amount of CO_2 that human activities can still release into the atmosphere while keeping global warming to a specified level, like 1.5°C or 2°C relative to pre-industrial temperatures. Emissions of CO_2 from human activities are the main cause of global warming. A remaining carbon budget can be defined because of the specific way CO_2 behaves in the Earth system. That is, global warming is roughly linearly proportional to the total net amount of CO_2 emissions that are released into the atmosphere by human activities – also referred to as cumulative anthropogenic CO_2 emissions. Other greenhouse gases behave differently and have to be accounted for separately.

The concept of a remaining carbon budget implies that to stabilize global warming at any particular level, global emissions of CO_2 need to be reduced to net zero levels at some point. Net zero CO_2 emissions describes a situation in which all the anthropogenic emissions of CO_2 are counterbalanced by deliberate anthropogenic removals so that on average no CO_2 is added or removed from the atmosphere by human activities. Atmospheric CO_2 concentrations in such a situation would gradually decline to a long-term stable level as excess CO_2 in the atmosphere is taken up ocean and land sinks (see FAQ 5.1). The concept of a remaining carbon budget also means that if CO_2 emissions reductions are delayed, deeper and faster reductions are needed later to stay within the same budget. If the remaining carbon budget is exceeded, this will result in either higher global warming or a need to actively remove CO_2 from the atmosphere to reduce global temperatures back down to the desired level (see FAQ 5.3).

Estimating the size of remaining carbon budgets depends on a set of choices. These choices include (1) the global warming level that is chosen as a limit (for example, 1.5°C or 2°C relative to pre-industrial levels), (2) the probability with which we want to ensure that warming is held below that limit (for example, a one-in-two, two-in-three, or higher chance), and (3) how successful we are in limiting emissions of other greenhouse gases that affect the climate, such as methane or nitrous oxide. These choices can be informed by science but ultimately represent subjective choices. Once they have been made, we can combine knowledge about how much our planet has warmed already, about the amount of warming per cumulative tonne of CO_2, and about the amount of warming that is still expected once global net CO_2 emissions are brought down to zero to estimate the remaining carbon budget for a given temperature goal. For example, to limit global warming to 1.5°C above pre-industrial levels with either a one-in-two (50%) or two-in-three (67%) chance, the remaining carbon budgets amount to 500 and 400 billion tonnes of CO_2, respectively, from 1 January 2020 onward (FAQ 5.4, Figure 1). Currently, human activities are emitting around 40 billion tonnes of CO_2 into the atmosphere in a single year.

The remaining carbon budget depends on how much the world has already warmed to date. This past warming is caused by historical emissions, which are estimated by looking at the *historical carbon budget* – a scientific way to describe all past and present sources and sinks of CO_2. It describes how the CO_2 emissions from human activities have redistributed across the various CO_2 reservoirs of the Earth system. These reservoirs are the ocean, the land vegetation, and the atmosphere (into which CO_2 was emitted). The share of CO_2 that is not taken up by the ocean or the land, and that thus increases the concentration of CO_2 in the atmosphere, causes global warming. The historical carbon budget tells us that of the about 2560 billion tonnes of CO_2 that were released into the atmosphere by human activities between the years 1750 and 2019, about a quarter were absorbed by the ocean (causing ocean acidification) and about a third by the land vegetation. About 45% of these emissions remain in the atmosphere (see FAQ 5.1). Adding these historical CO_2 emissions to estimates of remaining carbon budgets allows one to estimate the *total carbon budget*

ACCEPTED VERSION SUBJECT TO FINAL EDITS

consistent with a specific global warming level.

In summary, determining a remaining carbon budget – that is, how much CO_2 can be released into the atmosphere while stabilizing global temperature below a chosen level – is well understood but relies on a set of choices. What is clear, however, is that for limiting warming below 1.5°C or 2°C the remaining carbon budget from 2020 onwards is much smaller than the total CO_2 emissions released to date.

[START FAQ 5.4, FIGURE 1]

FAQ 5.4, Figure 1: Various types of carbon budgets. Historical cumulative CO_2 emissions determine to a large degree how much the world has warmed to date, while the remaining carbon budget indicates how much CO_2 could still be emitted while keeping warming below specific temperature thresholds. Several factors limit the precision with which the remaining carbon budget can be estimated, and estimates therefore need to specify the probability with which they aim at limiting warming to the intended target level (e.g., limiting warming to 1.5°C with a 67% probability).

ACCEPTED VERSION
SUBJECT TO FINAL EDITS

Figure 5.2: Key compartments, processes and pathways that govern historical and future CO_2 concentrations and carbon–climate feedbacks through the coupled earth system. The anthropogenic CO_2 emissions, including land use change, are partitioned via negative feedbacks (turquoise dotted arrows) between the ocean (23%), the land (31%) and the airborne fraction (46%) of anthropogenic CO_2 that sets the changing CO_2 concentration in the atmosphere (2010–2019, Table 5.1). This regulates most of the radiative forcing that creates the heat imbalance that drives the climate feedbacks to the ocean (blue) and land (green). Positive feedbacks (red arrows) result from processes in the ocean and on land (red text). Positive feedbacks are influenced by both carbon-concentration and carbon-climate feedbacks simultaneously. Additional biosphere processes have been included but these have an as yet uncertain feedback impact (blue-dotted arrows). CO_2 removal from the atmosphere into the ocean, land and geological reservoirs, necessary for negative emissions, has been included (grey arrows). Although this schematic is built around CO_2, the dominant GHG, some of the same processes also influence the fluxes of CH_4 and N_2O and the strength of the positive feedbacks from the terrestrial and ocean systems.

ACCEPTED VERSION SUBJECT TO FINAL EDITS

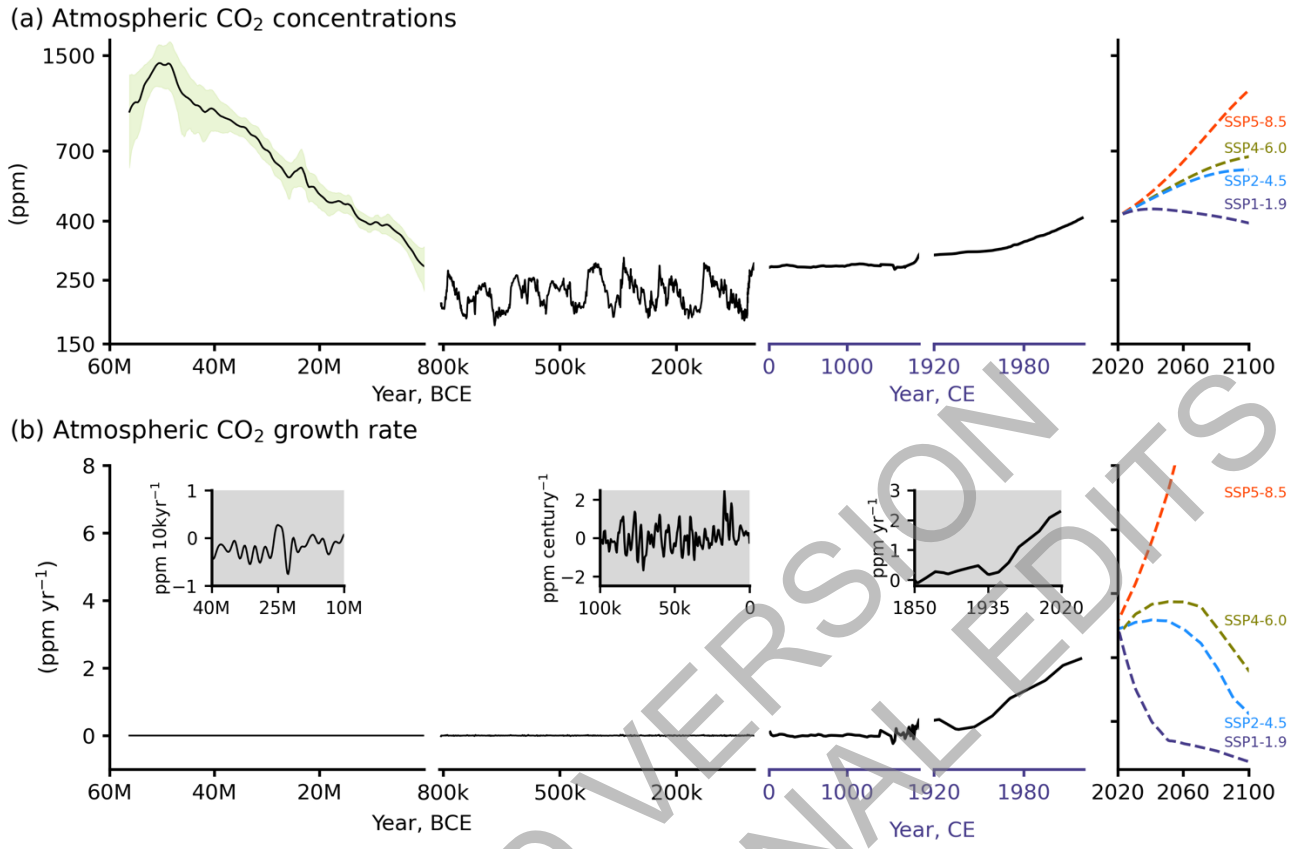

Figure 5.3: Atmospheric CO_2 concentrations and growth rates for the past 60 million years and projections to 2100. (a) CO_2 concentrations. Concentrations data for the period 60 Myr to the time prior to 800 Kyr (left column) are shown as the LOESS Fit and 68% range (data from Chapter 2) (Foster et al., 2017). Concentrations from 1750 and projections through 2100 are taken from Shared Socioeconomic Pathways of IPCC AR6 (Meinshausen et al., 2017). (b) Growth rates are shown as the time derivative of the concentration time series. Inserts in (b) show growth rates at the scale of the sampling resolution. Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

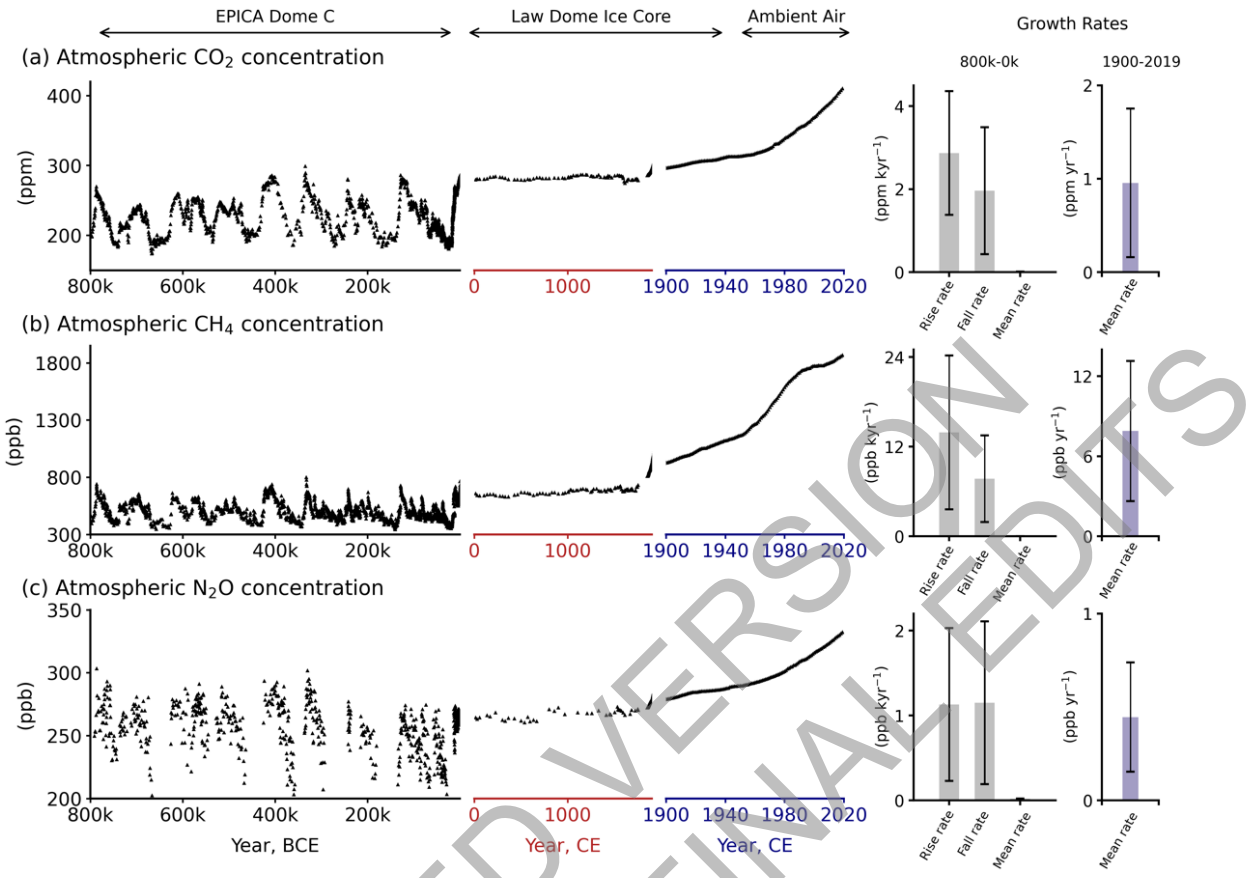

Figure 5.4: Atmospheric concentrations of CO_2, CH_4 and N_2O in air bubbles and clathrate crystals in ice cores (800,000 BCE to 1990 CE). Note the variable x-axis range and tick mark intervals for the 3 columns. Ice core data is over-plotted by atmospheric observations from 1958 to present for CO_2, from 1984 for CH_4 and from 1994 for N_2O. The time-integrated, millennial-scale linear growth rates for different time periods (800,000–0 BCE, 0–1900 CE and 1900–2017 CE) are given in each panel. For the BCE period, mean rise and fall rates are calculated for the individual slopes between the peaks (interglacials) and troughs (ice ages), which are given in the panels in left column. The data for BCE period are used from the Vostok, EPICA, Dome C and WAIS ice cores (Petit et al., 1999; Monnin, 2001; Pépin et al., 2001; Raynaud et al., 2005; Siegenthaler et al., 2005; Loulergue et al., 2008; Lüthi et al., 2008; Schilt et al., 2010a). The data after 0–yr CE are taken mainly from Law Dome ice core analysis (MacFarling Meure et al., 2006). The surface observations for all species are taken from NOAA cooperative research network (Dlugokencky and Tans, 2019), where ALT, MLO and SPO stand for Alert (Canada), Mauna Loa Observatory, and South Pole Observatory, respectively. BCE = before current era, CE = current era. Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

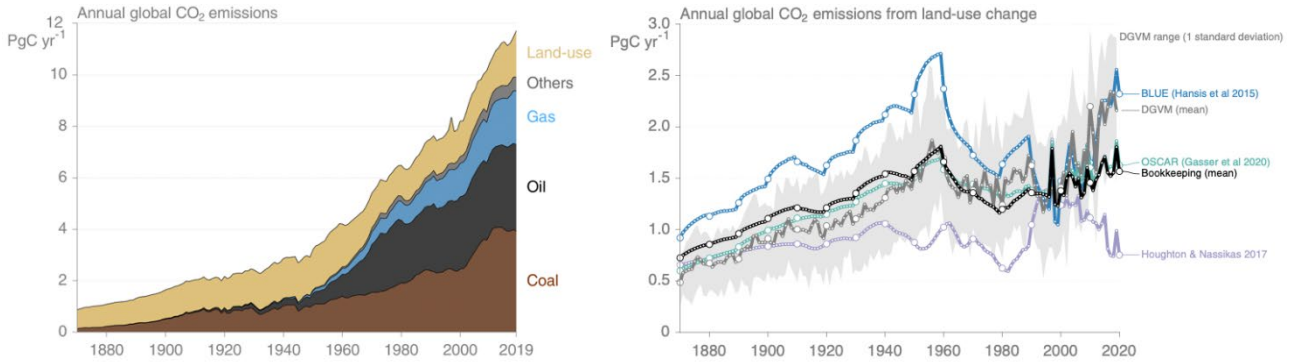

Figure 5.5: **Global anthropogenic CO_2 emissions**. (a) Historical trends of anthropogenic CO_2 emission (fossil fuels and net land use change, including land management, called LULUCF flux in the main text) for the period 1870 to 2019, with 'others' representing flaring, emissions from carbonates during cement manufacture. Data sources: (Boden et al., 2017; IEA, 2017; Andrew, 2018; BP, 2018; Le Quéré et al., 2018; Friedlingstein et al., 2020). (b) The net land use change CO_2 flux (PgC yr^{-1}) as estimated by three bookkeeping models and 16 Dynamic Global Vegetation Models (DGVMs) for the global annual carbon budget 2019 (Friedlingstein et al., 2020). The three bookkeeping models are from Hansis et al., 2015; Houghton and Nassikas, 2017; (Gasser et al., 2020) and are all updated to 2019; their average is used to determine the net land use change flux in the annual global carbon budget (black line). The DGVM estimates are the result of differencing a simulation with and without land use changes run under observed historical climate and CO_2, following the Trendy v9 protocol; they are used to provide an uncertainty range to the bookkeeping estimates (Friedlingstein et al., 2020). All estimates are unsmoothed annual data. Estimates differ in process comprehensiveness of the models and in definition of flux components included in the net land use change flux. Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

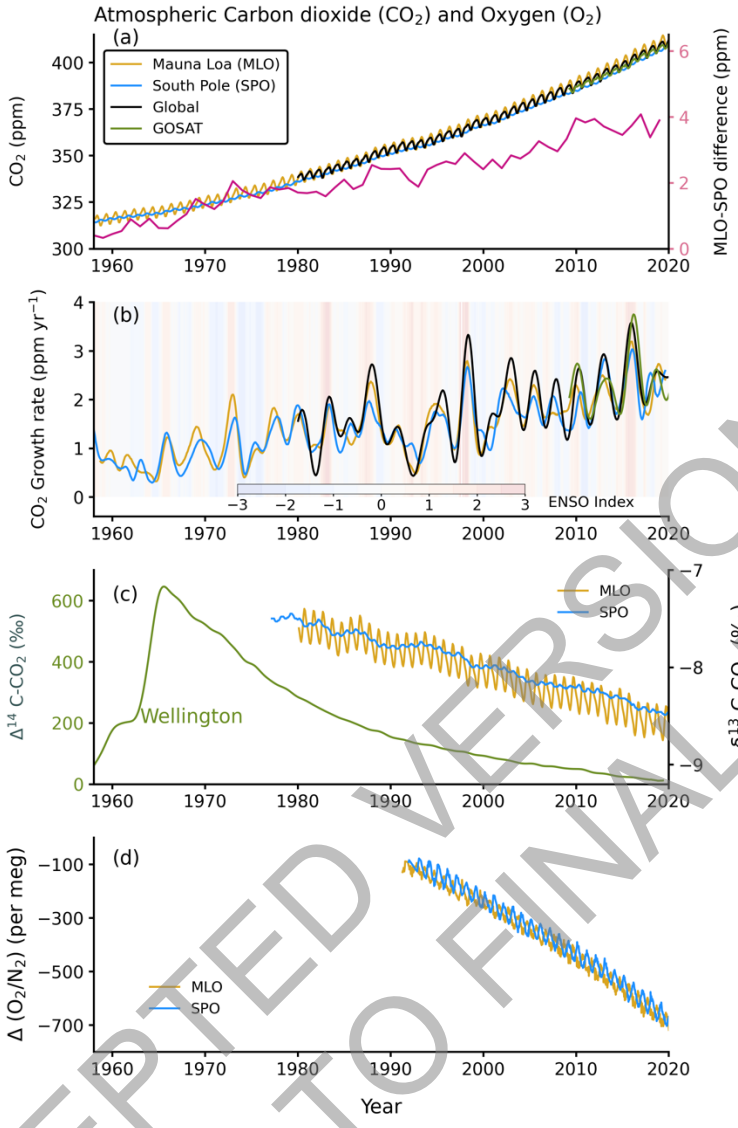

Figure 5.6: **Time series of CO_2 concentrations and related measurements in ambient air**. (a) concentration time series and MLO-SPO difference, (b) growth rates, (c) ^{14}C and ^{13}C isotopes, and (d) O_2/N_2 ratio. The data for Mauna Loa Observatory (MLO) and South Pole Observatory (SPO) are taken from the Scripps Institution of Oceanography (SIO)/University of California, San Diego (Keeling et al., 2001). The global mean CO_2 are taken from NOAA cooperative network (as in Chapter 2), and GOSAT monthly-mean XCO_2 time series are taken from National Institute for Environmental Studies (Yoshida et al., 2013). CO_2 growth rates are calculated as the time derivative of deseasonalised time series (Nakazawa et al., 1997). The $\Delta(O_2/N2)$ are expressed in per meg units (= $(FF/M)\times10^6$, where FF = moles of O_2 consumed by fossil-fuel burning, M = 3.706×10^{19}, total number of O_2 molecules in the atmosphere (Keeling and Manning, 2014).The $^{14}CO_2$ time series at Barring Head, Wellington, New Zealand (BHD) is taken from GNS Science and NIWA (Turnbull et al., 2017). The multivariate ENSO index (MEI) is shown as the shaded background in panel (b; warmer shade indicates El Niño). Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

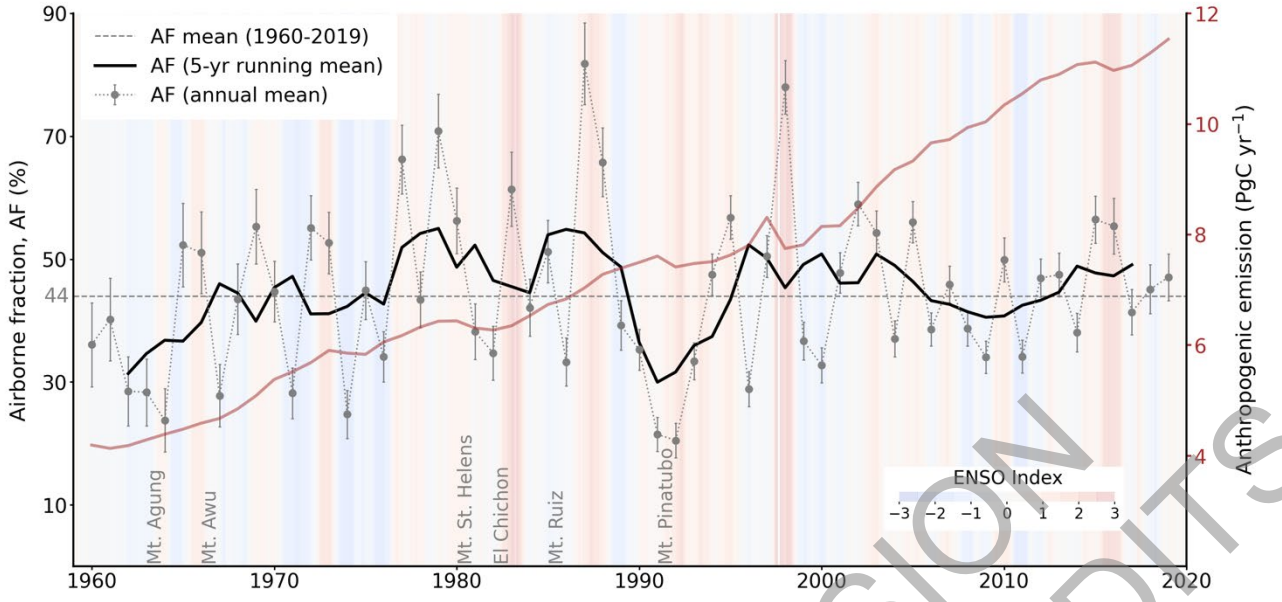

Figure 5.7: **Airborne fraction and anthropogenic (fossil fuel and land use change) CO_2 emissions**. Data as in Section 5.2.1.1. The multivariate ENSO index (shaded) and the major volcanic eruptions are marked along the x-axis. Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

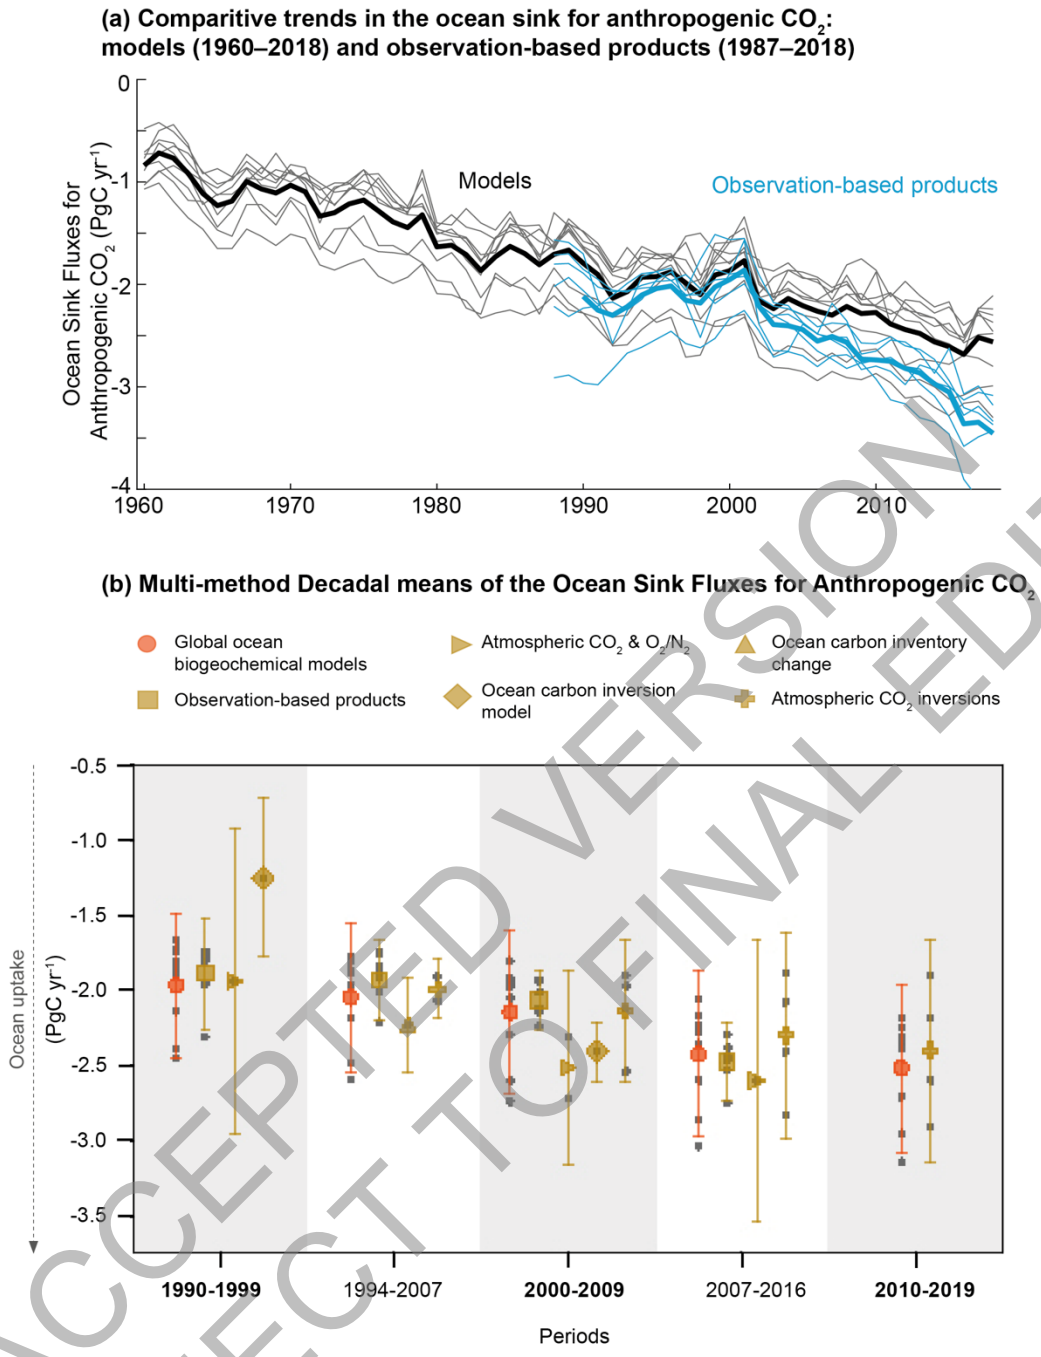

Figure 5.8: Multi-decadal trends for the ocean sink of CO_2. (a): The multi-decadal (1960–2019) trends in the annual ocean sink (S_{ocean}) reconstructed from 9 Global Ocean Biogeochemical Models (GOBM) forced with observed atmospheric re-analysis products (Hauck et al., 2020), 6 observationally-based gap-filling products that reconstructed spatial and temporal variability in the ocean CO_2 flux from sparse observations of surface ocean pCO_2 (Supplementary Materials 5.SM.2). The trends in S_{ocean} were calculated from the mean annual global GOBM outputs and the observational products were used to provide confidence in the GOBM assessments (r^2=0.85). Thick lines represent the multi-model mean. Observationally-based products have been corrected for pre-industrial river carbon fluxes (0.62 $PgC\ yr^{-1}$) based on the average of estimates from Jacobson et al., (2007) and Resplandy et al. (2018). (b): Mean decadal constraints and their confidence intervals for global ocean sink (S_{ocean}) of anthropogenic CO_2 using multiple independent or quasi-independent lines of evidence or methods for the period 1990–2019 (See Supplementary Materials Tables 5.SM.1 and 5.SM.2 for magnitudes, uncertainties and published sources). Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

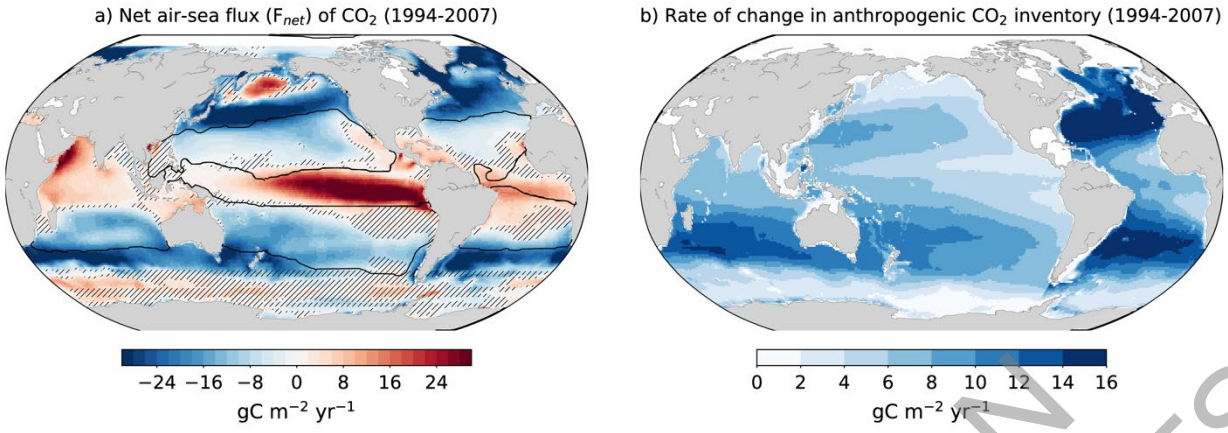

Figure 5.9: Comparative regional characteristics of the mean decadal (1994–2007) sea-air CO_2 flux (F_{net}) and ocean storage of anthropogenic CO_2. (a) regional sink–source characteristics for contemporary ocean air-sea CO_2 fluxes (F_{net}) derived from the ensemble of 6 observation-based products using SOCATv6 observational data set (Bakker et al., 2020; Landschützer et al., 2014; Rödenbeck eta l., 2014; Zeng et al., 2014; Denvil-Sommer et al., 2019; Gregor et al., 2019; Iida et al., 2020) Warm colours depict outgassing fluxes and black contours characterise the super-biomes defined from Fay and McKinley (2014) and adjusted by Gregor et al., (2019) also used to calculate the variability in regional flux anomalies (Supplementary Materials Figure 5.SM.1); and (b) the regional characteristics of the storage fluxes of CO_2 in the ocean interior for the same period (Gruber et al., 2019a). The dots reflect ocean areas where the 1-sigma standard deviation of Fnet from the 6 observation product is larger than the magnitude of the mean. This reflects source-sink transition areas where the mean Fnet is small and more strongly influenced by spatial and temporal variability across the products. Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

SUBJECT TO FINAL EDITS

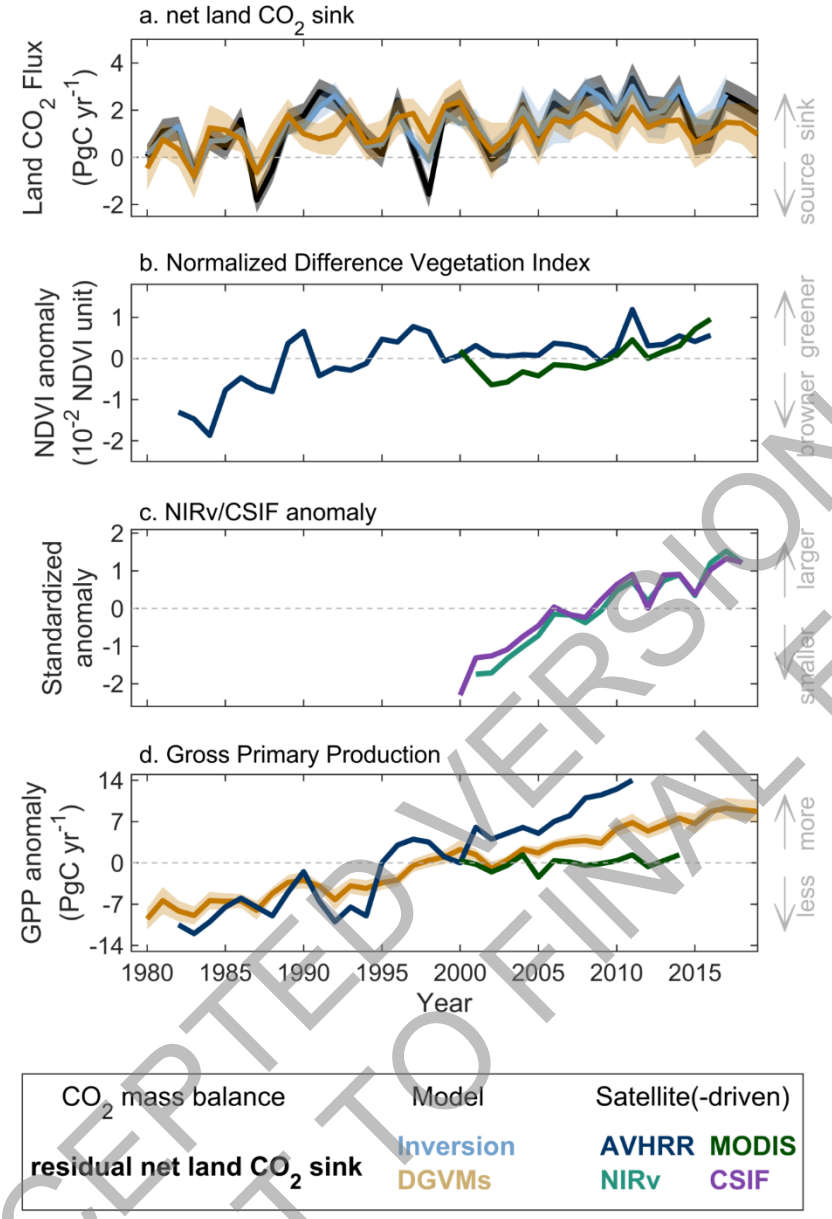

Figure 5.10: Trends of the net land CO_2 sink and related vegetation observations during 1980–2019. (a) Net land CO_2 sink. The residual net land CO_2 sink is estimated from the global CO_2 mass balance (fossil fuel emission minus atmospheric CO_2 growth rate and ocean CO_2 sink). Inversions indicate the net land CO_2 sink estimated by an ensemble of four atmospheric inversions. Dynamic Global Vegetation Models (DGVMs) indicate the mean net land CO_2 sink estimated by 17 dynamic global vegetation models driven by climate change, rising atmospheric CO_2, land use change and nitrogen deposition change (for carbon-nitrogen models). The positive values indicate net CO_2 uptake from the atmosphere. (b) Normalised difference vegetation index (NDVI). The anomaly of global area-weighted NDVI observed by AVHRR and MODIS satellite sensors. AVHRR data are accessible during 1982–2016 and MODIS data are accessible during 2000–2018. (c) Near-infrared reflectance of vegetation (NIRv) and contiguous solar-induced chlorophyll fluorescence (CSIF). The standardised anomaly of area-weighted NIRv during 2001-2018 (Badgley et al., 2017) and CSIF during 2000-2018 (Zhang et al., 2018). (d) Gross primary production (GPP). The GPP from Cheng et al. (2017), DGVMs and MODIS GPP product (MOD17A3). GPP from Cheng et al. (2017) is based on an analytical model driven by climate change, rising atmospheric CO_2, AVHRR leaf area index datasets and evapotranspiration datasets. GPP from DGVMs is the ensemble mean global GPP estimated by the same 17 DGVMs that provide the net land CO_2 sink estimates. Shaded area indicates 1–σ inter-model spread except for atmospheric inversions, whose ranges were used due to limited number of models. Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

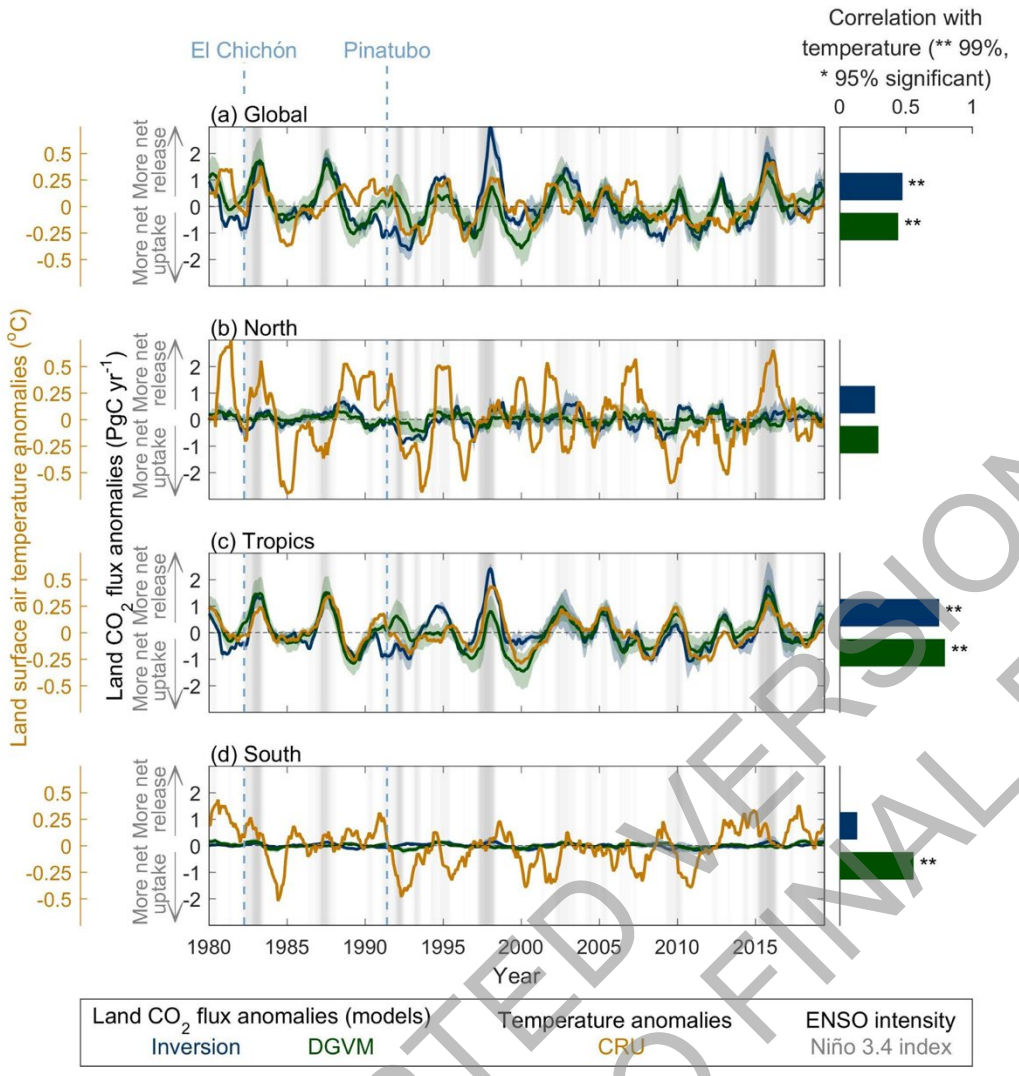

Figure 5.11: Interannual variation in detrended anomalies of the net land CO_2 sink and land surface air temperature during 1980–2019. Correlation coefficients between the net land CO_2 sink anomalies and temperature anomalies are show on the right bar plots. The net land CO_2 sink is estimated by four atmospheric inversions (blue) and fifteen Dynamic Global Vegetation Models (DGVMs) (green), respectively (Friedlingstein et al., 2020). Solid blue and green lines show model mean detrended anomalies of the net land CO_2 sink. The ensemble mean of DGVMs is bounded by the 1–σ inter-model spread in each large latitude band (North 30°N–90°N, Tropics 30°S–30°N, South 90°S–30°S) and the globe. The ensemble mean of atmospheric inversions is bounded by model spread. For each latitudinal band, the anomalies of the net land CO_2 sink and temperature (orange) were obtained by removing the long-term trend and seasonal cycle. A 12-month running mean was taken to reduce high-frequency noise. The bars in the right panels show correlation coefficients between the net land CO_2 sink anomalies and temperature anomalies for each region. Two asterisks indicate P<0.01, and one indicates P<0.05. Grey shaded area shows the intensity of El Niño southern oscillation (ENSO) as defined by the Niño 3.4 index. Two volcanic eruptions (El Chichón eruption and Pinatubo eruption) are indicated with light blue dashed lines. Temperature data are from the Climatic Research Unit (CRU), University of East Anglia (Harris et al., 2014). Anomalies were calculated following Patra et al. (2005), but using 12-month low-pass filter and detrended to obtain interannual variations. Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

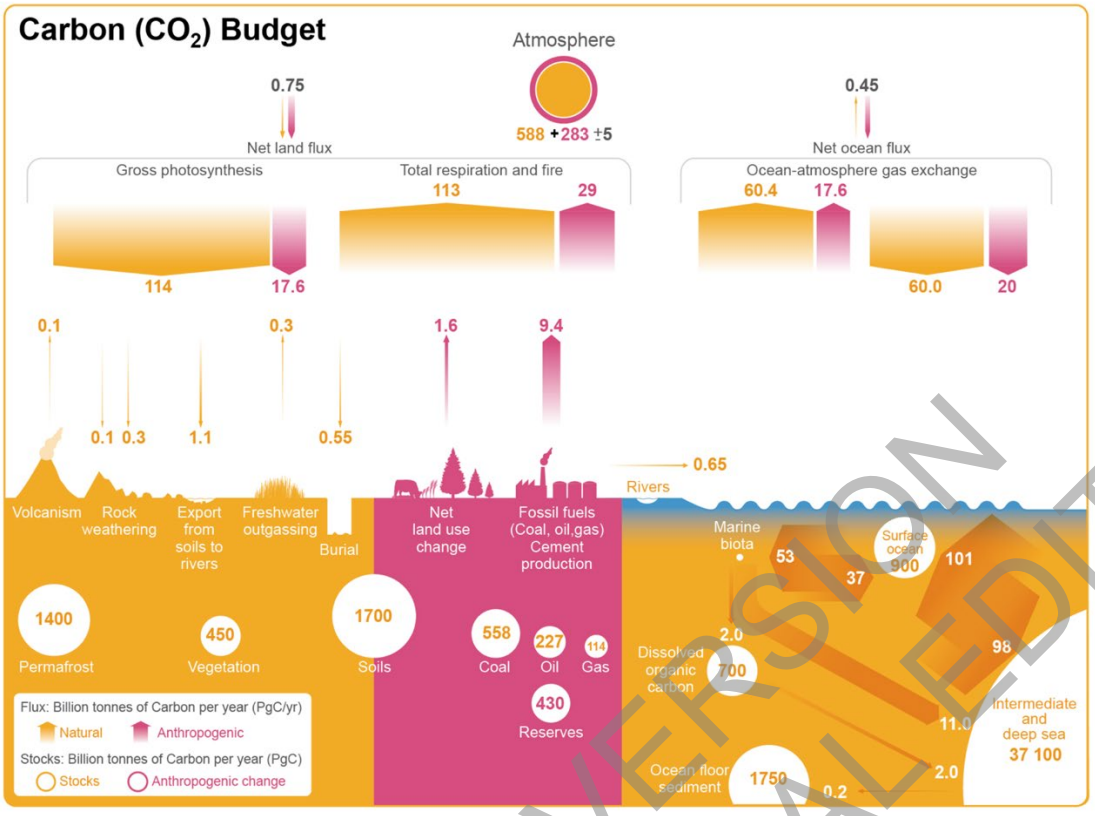

Figure 5.12: Global carbon (CO_2) budget (2010-2019). Yellow arrows represent annual carbon fluxes (in PgC yr^{-1}) associated with the natural carbon cycle estimated for the time prior to the industrial era, around 1750. Pink arrows represent anthropogenic fluxes averaged over the period 2010–2019. The rate of carbon accumulation in the atmosphere is equal to net land-use change emissions, including land management (called LULUCF in the main text) plus fossil fuel emissions, minus land and ocean net sinks (plus a small budget imbalance, Table 5.1). Circles with yellow numbers represent pre-industrial carbon stocks in PgC. Circles with pink numbers represent anthropogenic changes to these stocks (cumulative anthropogenic fluxes) since 1750. Anthropogenic net fluxes are reproduced from Friedlingstein et al., (2020). The relative change of *gross photosynthesis* since pre-industrial times is based on 15 DGVMs used in Friedlingstein et al., (2020). The corresponding emissions by *Total respiration and fire* are those required to match the *net land flux*, exclusive of net land-use change emissions which are accounted for separately. The cumulative change of anthropogenic carbon in the terrestrial reservoir is the sum of carbon cumulatively lost by net land use change emissions, and net carbon accumulated since 1750 in response to environmental drivers (warming, rising CO_2, nitrogen deposition). The adjusted gross natural ocean-atmosphere CO_2 flux was derived by rescaling the value in figure 1 of (Sarmiento and Gruber, 2002) of 70 PgC/yr by the revised estimate of the bomb ^{14}C inventory in the ocean. The original bomb ^{14}C inventoy yielded an average global gas transfer velocity of 22 cm/hr; the revised estimate is 17cm/h leading to 17/22*70=54. Dissolved organic carbon reservoir and fluxes from (Hansell et al., 2009). Dissolved inorganic carbon exchanges between surface and deep ocean, subduction and obduction from (Levy et al., 2013) Levy et al. 2013. Export production and flux from (Boyd et al., 2019). NPP and remineralisation in surface layer of the ocean from (Kwiatkowski et al., 2020; Séférian et al., 2020). Deep ocean reservoir from (Keppler et al., 2020). Note that the mass balance of the two ocean carbon stocks *surface ocean* and *intermediate and deep ocean* includes a yearly accumulation of anthropogenic carbon (not shown). Fossil fuel reserves are from (BGR, 2019); fossil fuel resources are 11,490 PgC for coal, 6,780 PgC for oil, and 365 PgC for natural gas. Permafrost region stores are from (Hugelius et al., 2014; Strauss et al., 2017; Mishra et al., 2021) (see also Box 5.1) and soil carbon stocks outside of permafrost region from Batjes, (2016); Jackson et al., (2017). Biomass stocks (range of seven estimates) are from Erb et al., (2018). Sources for the fluxes of the continuum land-to-ocean are provided in main text and adjusted within the ranges of the various assessment to balance the budget (section 5.2.1.5).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

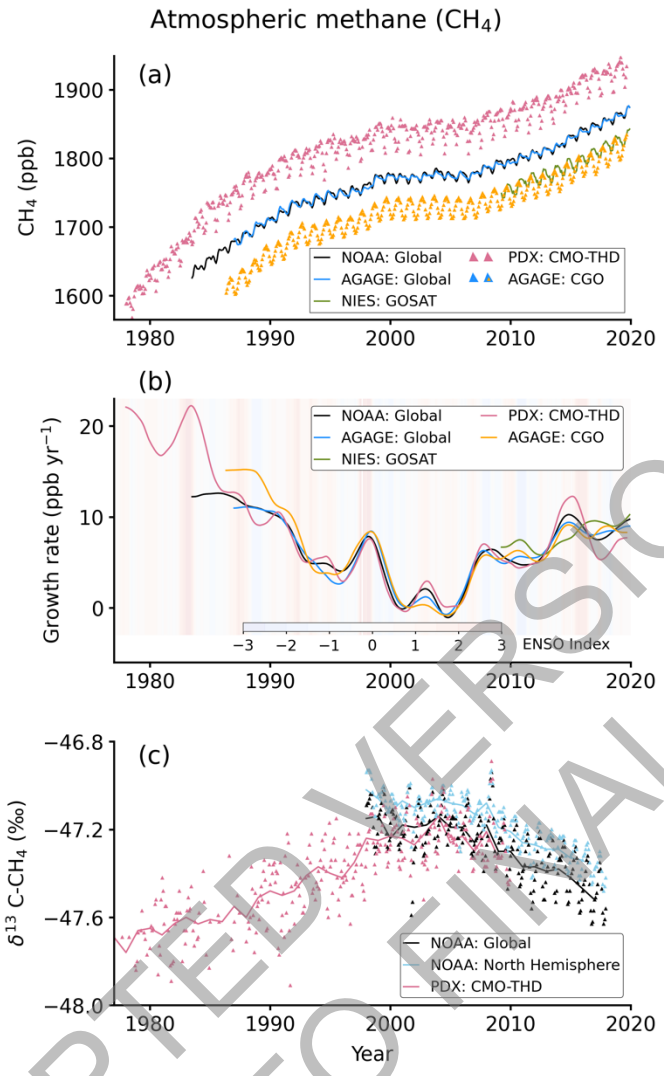

Figure 5.13: Time series of CH_4 concentrations, growth rates and isotopic composition. a) CH_4 concentrations, b) CH_4 growth rates, c) δ^{13}-CH_4. Data from selected site networks operated by NOAA (Dlugokencky et al., 2003), AGAGE (Prinn et al., 2018) and PDX (Portland State University) (Rice et al., 2016). To maintain clarity, data from many other measurement networks are not included here, and all measurements are shown in WMO X2004ACH_4 global calibration standard. Global mean values of XCH_4 (total-column), retrieved from radiation spectra measured by the greenhouse gases observation satellite (GOSAT) are shown in panels (a) and (b). Cape Grim Observatory (CGO; 41°S, 145°E) and Trinidad Head (THD; 41°N, 124°W) data are taken from the AGAGE network, NOAA global and northern hemispheric (NH) means for δ^{13}C are calculated from 10 and 6 sites, respectively. The PDX data adjusted to NH (period: 1977–2000) are merged with THD (period: 2001–2019) for CH_4 concentration and growth rate analysis, and PDX and NOAA NH means of δ^{13}C data are used for joint interpretation of long-term trends analysis. The multivariate ENSO index (MEI) is shown in panel (b). Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

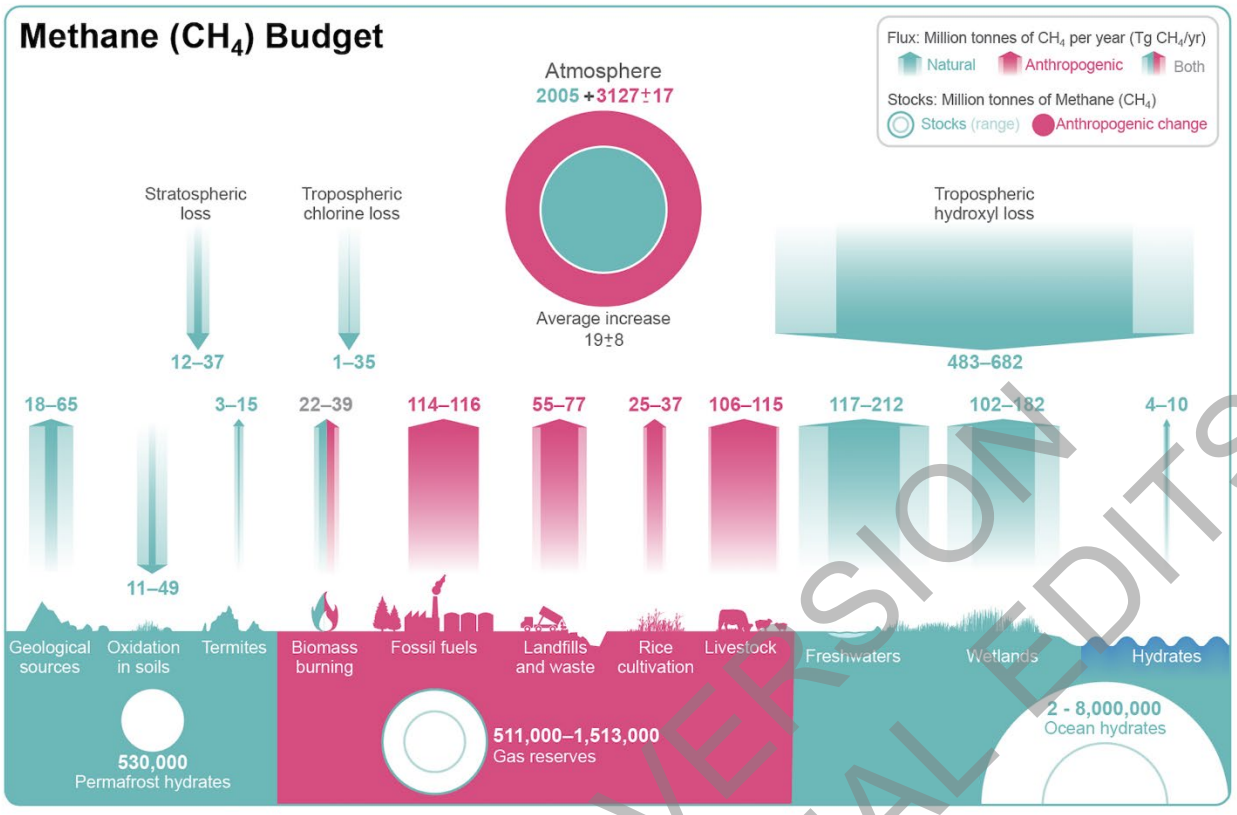
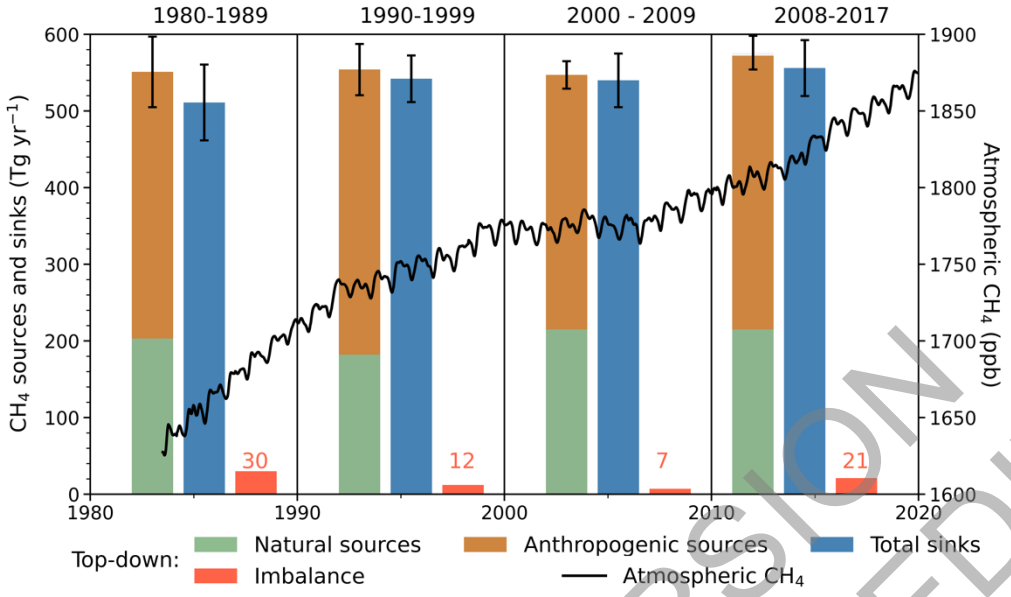
ACCEPTED VERSION SUBJECT TO FINAL EDITS





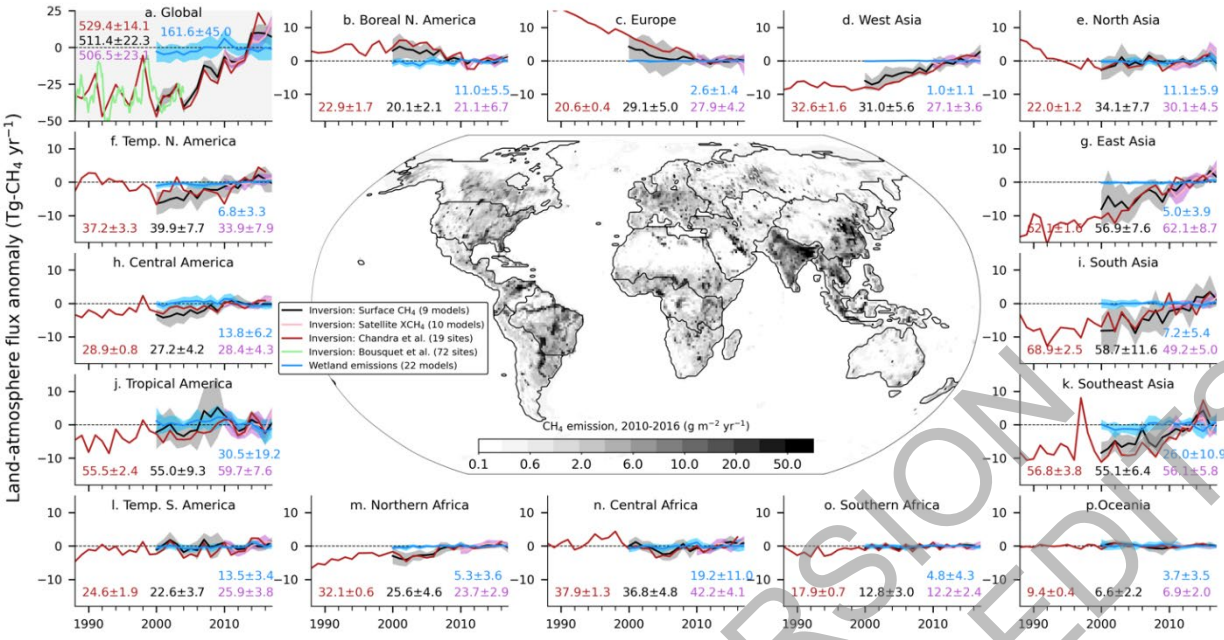


Figure 5.14: Global methane (CH_4) budget (2008–2017). Values and data sources as in Table 5.2 (in TgCH_4). The atmospheric stock is calculated from mean CH_4 concentration, multiplying a factor of 2.75 ± 0.015 Tg ppb^{-1}, which accounts for the uncertainties in global mean CH_4 (Chandra et al., 2021). Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Cross-Chapter Box 5.2, Figure 1: **Methane sources and sinks for four decades from atmospheric inversions with the budget imbalance** (source-sink; red bars) (plotted on the left y-axis). Top-down analysis from (Kirschke et al., 2013; Saunois et al., 2020), The global CH_4 concentration seen in the black line (plotted on the right y-axis), representing NOAA observed global monthly mean atmospheric CH_4 in dry-air mole fractions for 1983–2019 (Chapter 2, Annex V). Natural sources include emissions from natural wetlands, lakes and rivers, geological sources, wild animals, termites, wildfires, permafrost soils, and oceans. Anthropogenic sources include emissions from enteric fermentation and manure, landfills, waste and wastewater, rice cultivation, coal mining, oil and gas industry, biomass and biofuel burning. The top-down total sink is determined from global mass balance includes chemical losses due to reactions with hydroxyl (OH), atomic chlorine (Cl), and excited atomic oxygen (O^1D), and oxidation by bacteria in aerobic soils (Table 5.2). Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Cross-Chapter Box 5.2, Figure 2: Anomalies in global and regional methane (CH_4) emissions for 1988–2017. Map in the centre shows mean CH_4 emission for 2010–2016 . Multi-model mean (line) and 1-σ standard deviations (shaded) for 2000–2017 are shown for 9 surface CH_4 and 10 satellite XCH_4 inversions, and 22 wetland models or model variants that participated in GCP-CH_4 budget assessment (Saunois et al., 2020). The results for the period before 2000 are available from two inversions, 1) using 19 sites (Chandra et al., 2021; also used for the 2010-2016 mean emission map) and for global totals (Bousquet et al., 2006). The long-term mean values for 2010-2016 (common for all GCP–CH_4 inversions), as indicated within each panel separately, is subtracted from the annual-mean time series for the calculation of anomalies for each region. Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

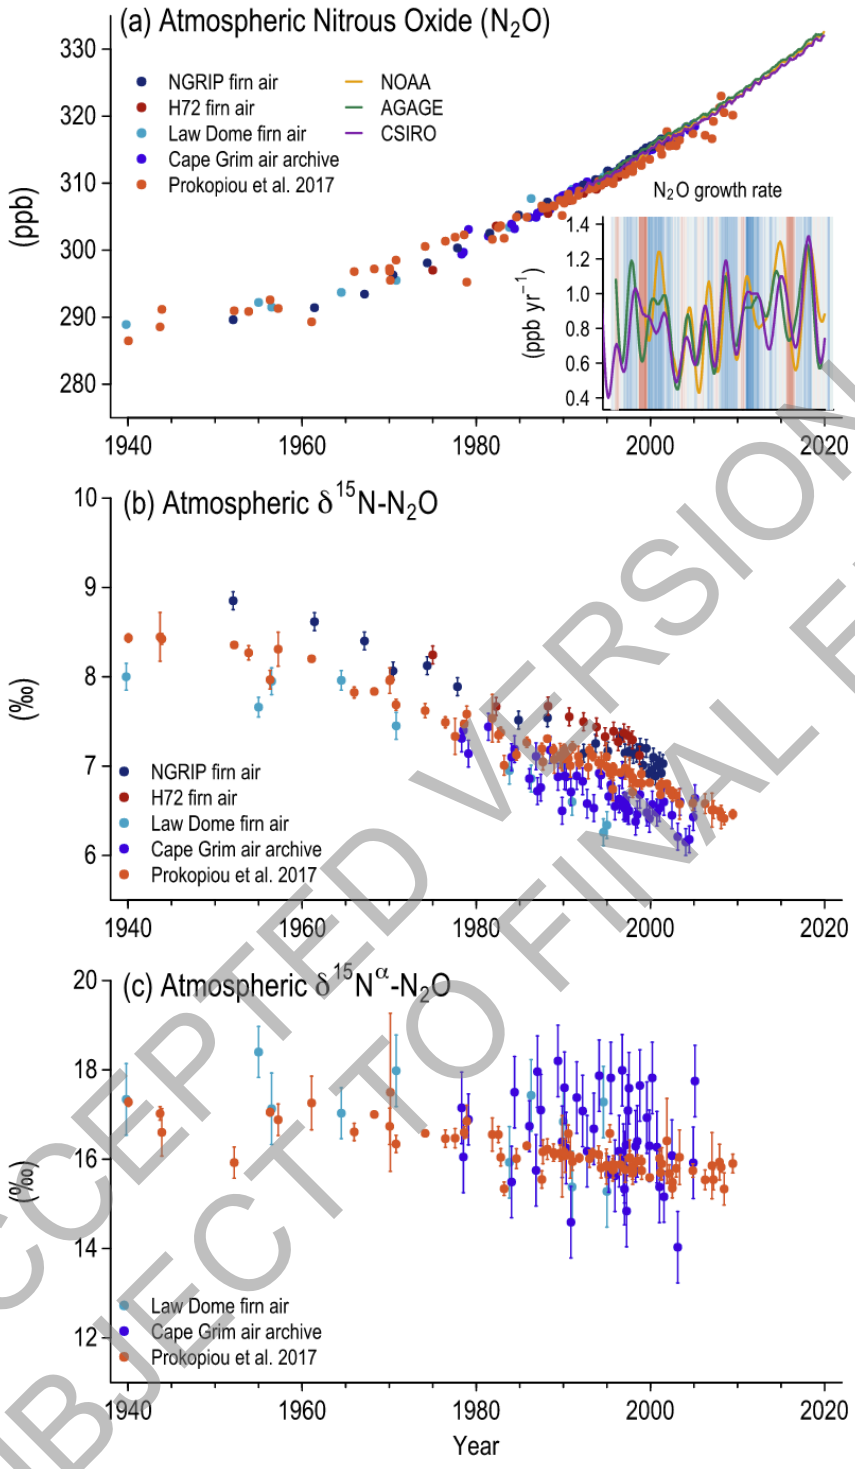

Figure 5.15: Changes in atmospheric nitrous oxide (N_2O) and its isotopic composition since 1940. (a) Atmospheric N_2O abundance (parts per billion, ppb) and growth rate (ppb yr^{-1}), (b) $\delta^{15}N$ of atmospheric N_2O, and (c) alpha-site ^{15}N–N_2O. Estimate are based on direct atmospheric measurements in the AGAGE , CSIRO, and NOAA networks (Prinn et al., 2000, 2018; Francey et al., 2003; Hall et al., 2007; Elkins et al., 2018), archived air samples from Cape Grim, Australia (Park et al., 2012), and firn air from NGRIP Greenland and H72 Antarctica (Ishijima et al., 2007), Law Dome Antarctica (Park et al., 2012), as well as a collection of firn ice samples from Greenland (Prokopiou et al., 2017, 2018). Shading in (a) is based on the multivariate ENSO index, with red indicating El Niño conditions (Wolter and Timlin, 1998). Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

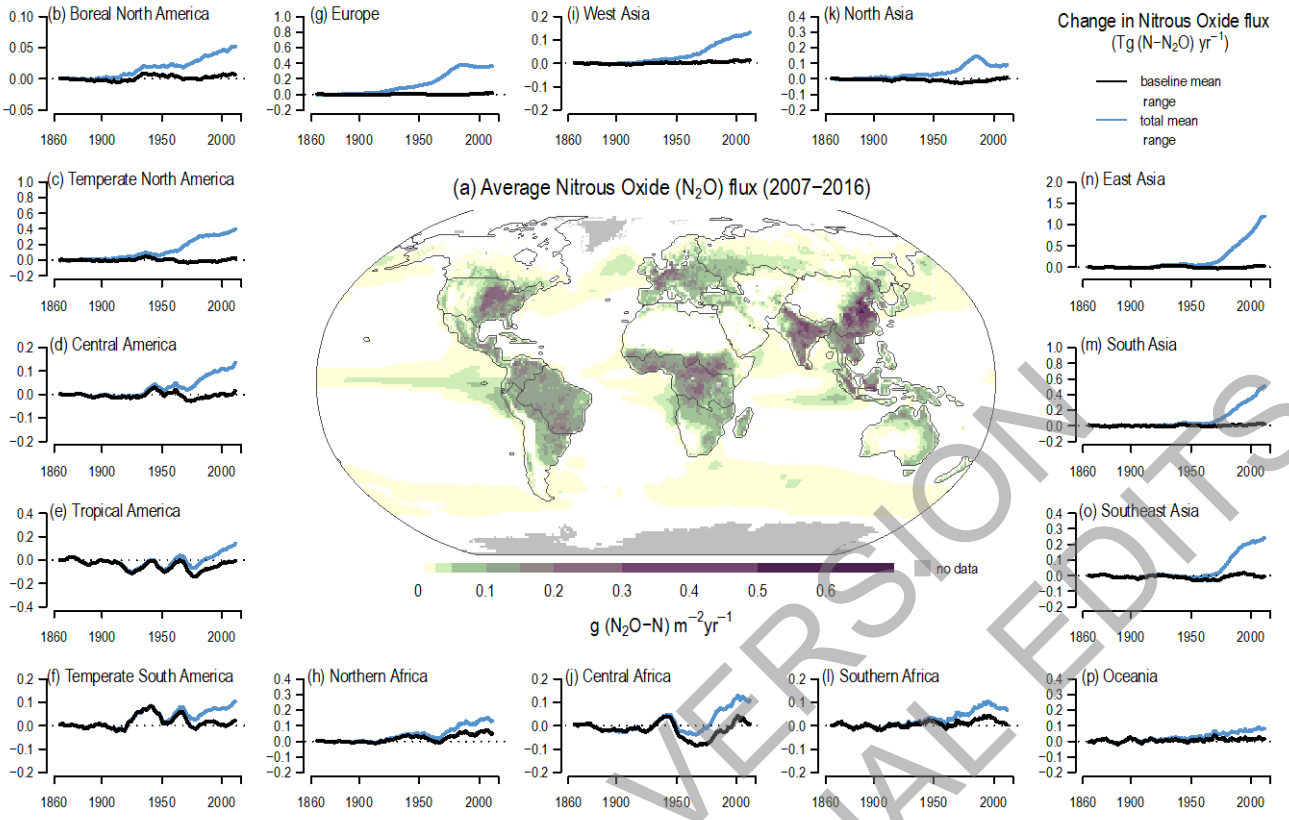

Figure 5.16: Decadal mean nitrous oxide (N_2O) emissions for 2007–2016 and its change since 1850 based on process-model projections. The total effect including that from anthropogenic nitrogen additions (atmospheric deposition, manure addition, fertiliser use and land-use) is evaluated against the background flux driven by changes in atmospheric CO_2 concentration, and climate change. Fluxes are derived from the N_2O Model Intercomparison Project ensemble of terrestrial biosphere models (Tian et al., 2019) and three ocean biogeochemical models (Landolfi et al., 2017; Battaglia and Joos, 2018a; Buitenhuis et al., 2018). Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

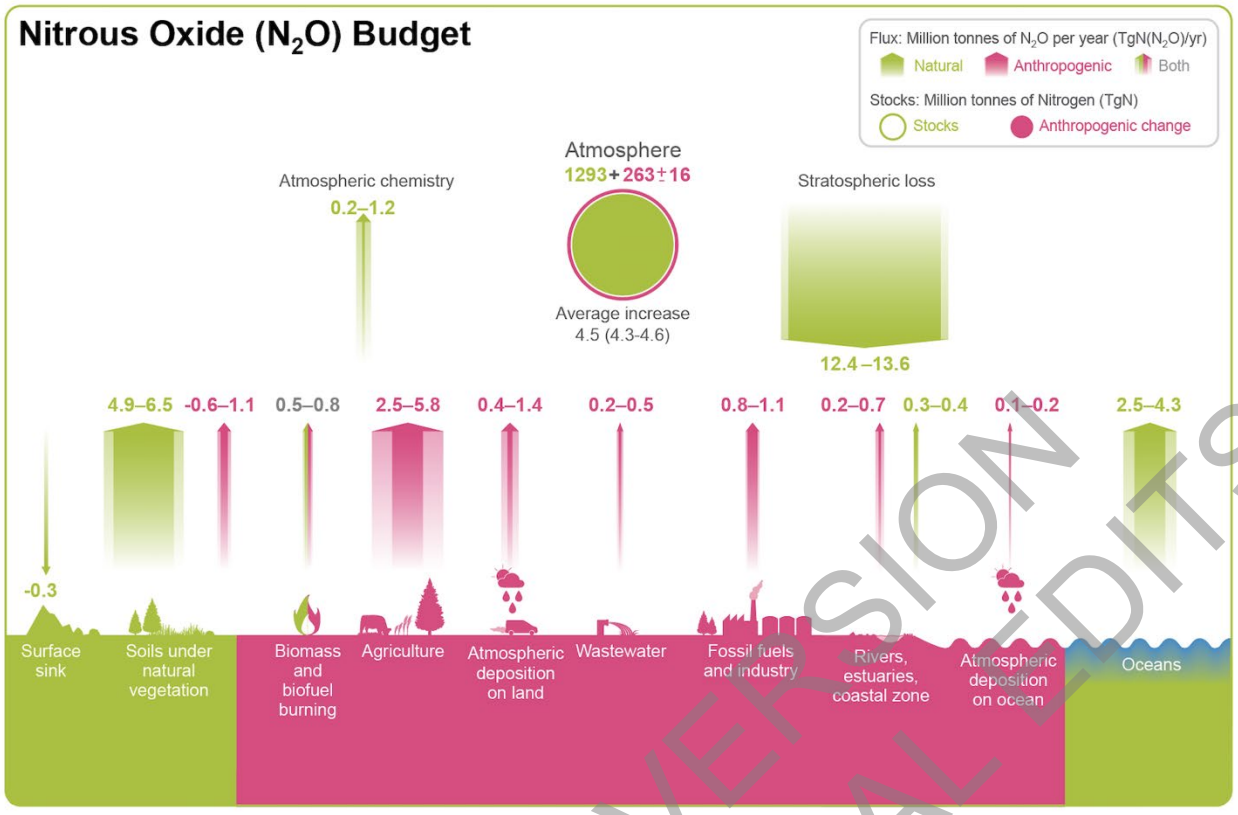

Figure 5.17: Global nitrous oxide (N_2O) budget (2007–2016). Values and data sources as in Table 5.3. The atmospheric stock is calculated from mean N_2O concentration, multiplying a factor of 4.79 ± 0.05 Tg ppb^{-1} (Prather et al., 2012). Pool sizes for the other reservoirs are largely unknown. Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

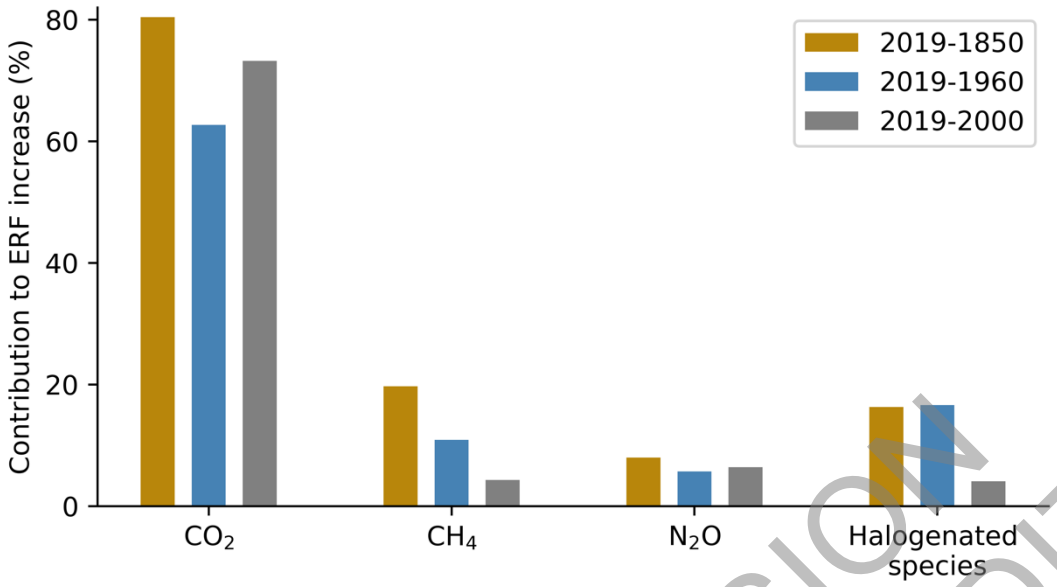

Figure 5.18: Contributions of carbon dioxide (CO_2), methane (CH_4), nitrous oxide (N_2O) and halogenated species to the total effective radiative forcing (ERF) increase since 1850 and 1960, and for 2000 to 2009. ERF data are taken from Annex 5 (based on calculations from Chapter 7). Note that the sum of the ERFs exceeds 100% because there are negative ERFs due to aerosols and clouds. Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

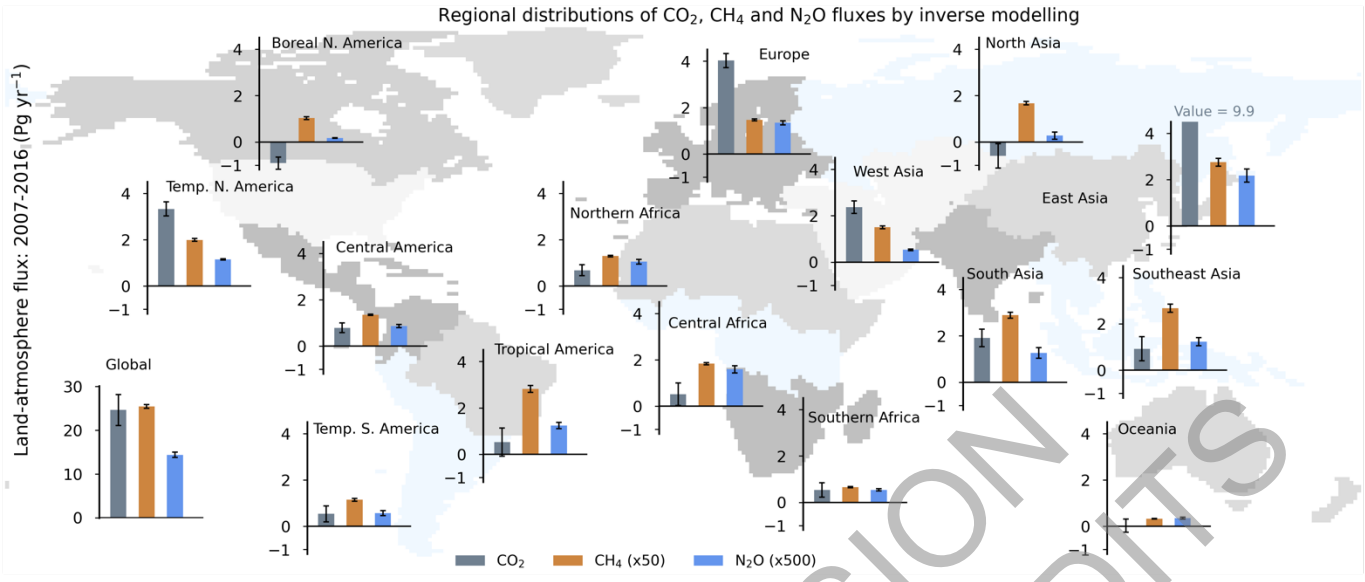

Figure 5.19: Regional distributions of net fluxes of carbon dioxide (CO_2), methane (CH_4), nitrous oxide (N_2O) on the Earth's surface. The region divisions, shown as the shaded map, are made based on ecoclimatic characteristics of the land. The fluxes include those from anthropogenic activities and natural causes that result from responses to anthropogenic greenhouse gases and climate forcing (feedbacks) as in the three budgets shown in Sections 5.2.1.5, 5.2.2.5, and 5.2.3.5. The CH_4 and N_2O emissions are weighted by arbitrary factors of 50 and 500, respectively, for depiction by common y-axes. Fluxes are shown as the mean of the inverse models as available from (Thompson et al., 2019; Friedlingstein et al., 2020; Saunois et al., 2020). Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

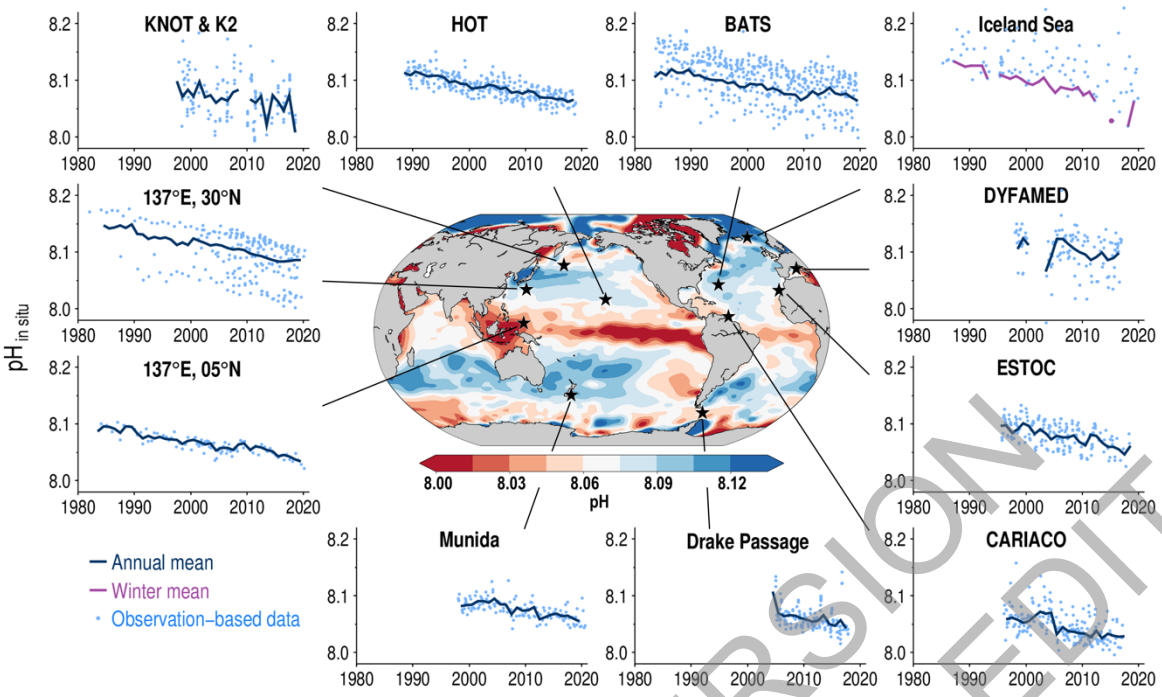

Figure 5.20: Multi-decadal trends of pH (Total Scale) in surface layer at various sites of the oceans and a global distribution of annual mean pH adjusted to the year 2000. Time-series data of pH are from Dore et al., 2009; Olafsson et al., 2009; González-Dávila et al., 2010; Bates et al., 2014b; Takahashi et al., 2014; Wakita et al., 2017; Merlivat et al., 2018; Ono et al., 2019; and Bates and Johnson, 2020. Global distribution of annual mean pH have been evaluated from data of surface ocean pCO_2 measurements (Bakker et al., 2016; Jiang et al., 2019). Acronyms in panels: KNOT and K2 - Western Pacific subarctic gyre time-series; HOT - Hawaii Ocean Time-series; BATS - Bermuda Atlantic Time-series Study; DYFAMED - Dynamics of Atmospheric Fluxes in the Mediterranean Sea; ESTOC - European Station for Time-series in the Ocean Canary Islands; CARIACO - Carbon Retention in a Colored Ocean Time-series. Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

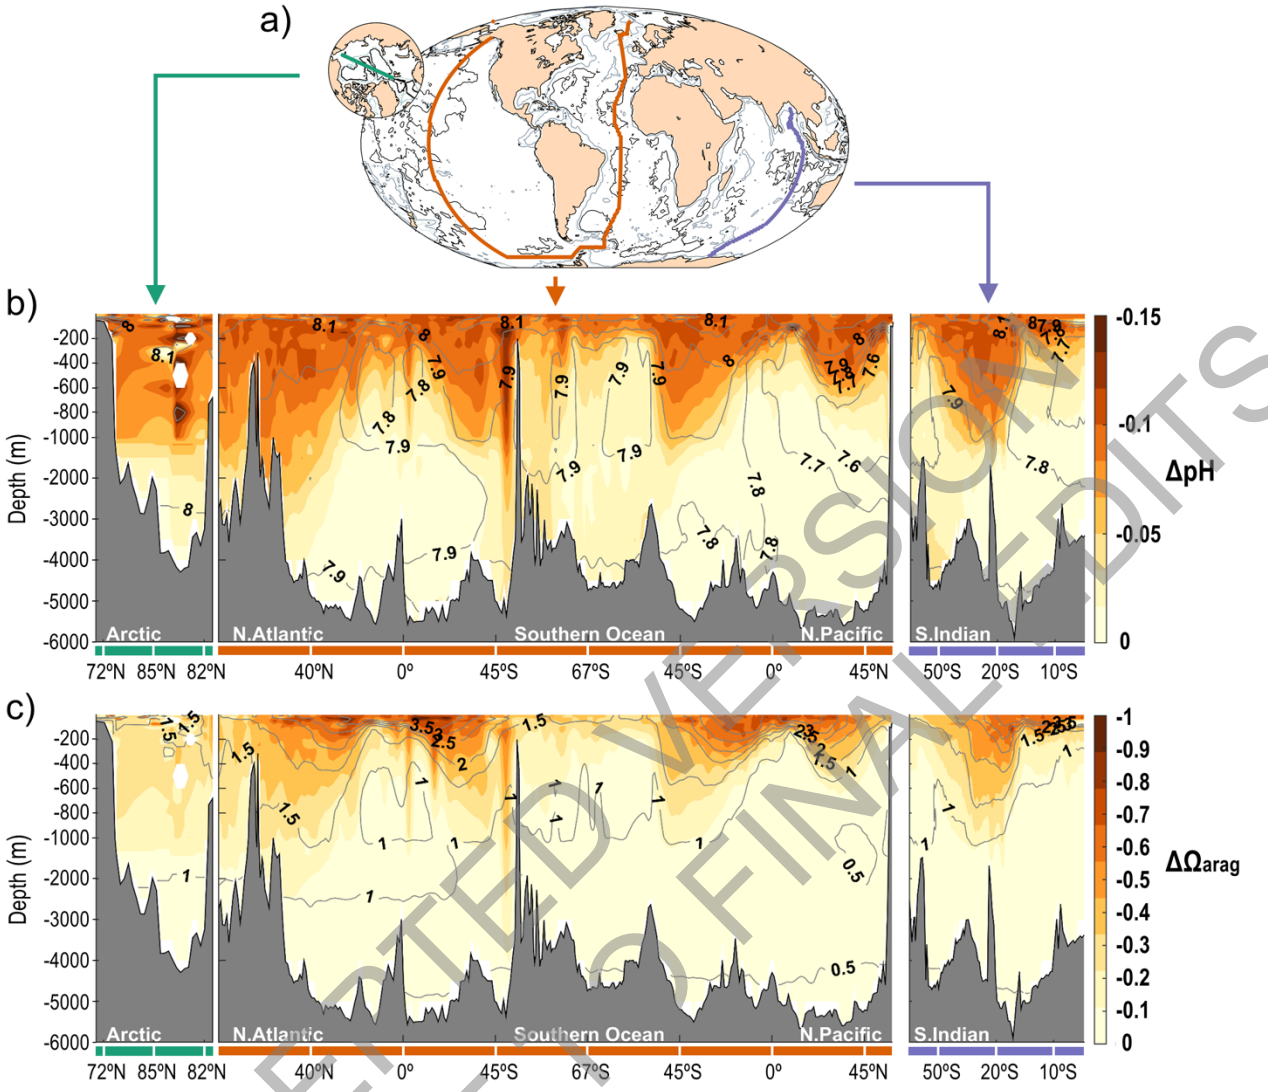
ACCEPTED VERSION SUBJECT TO FINAL EDITS



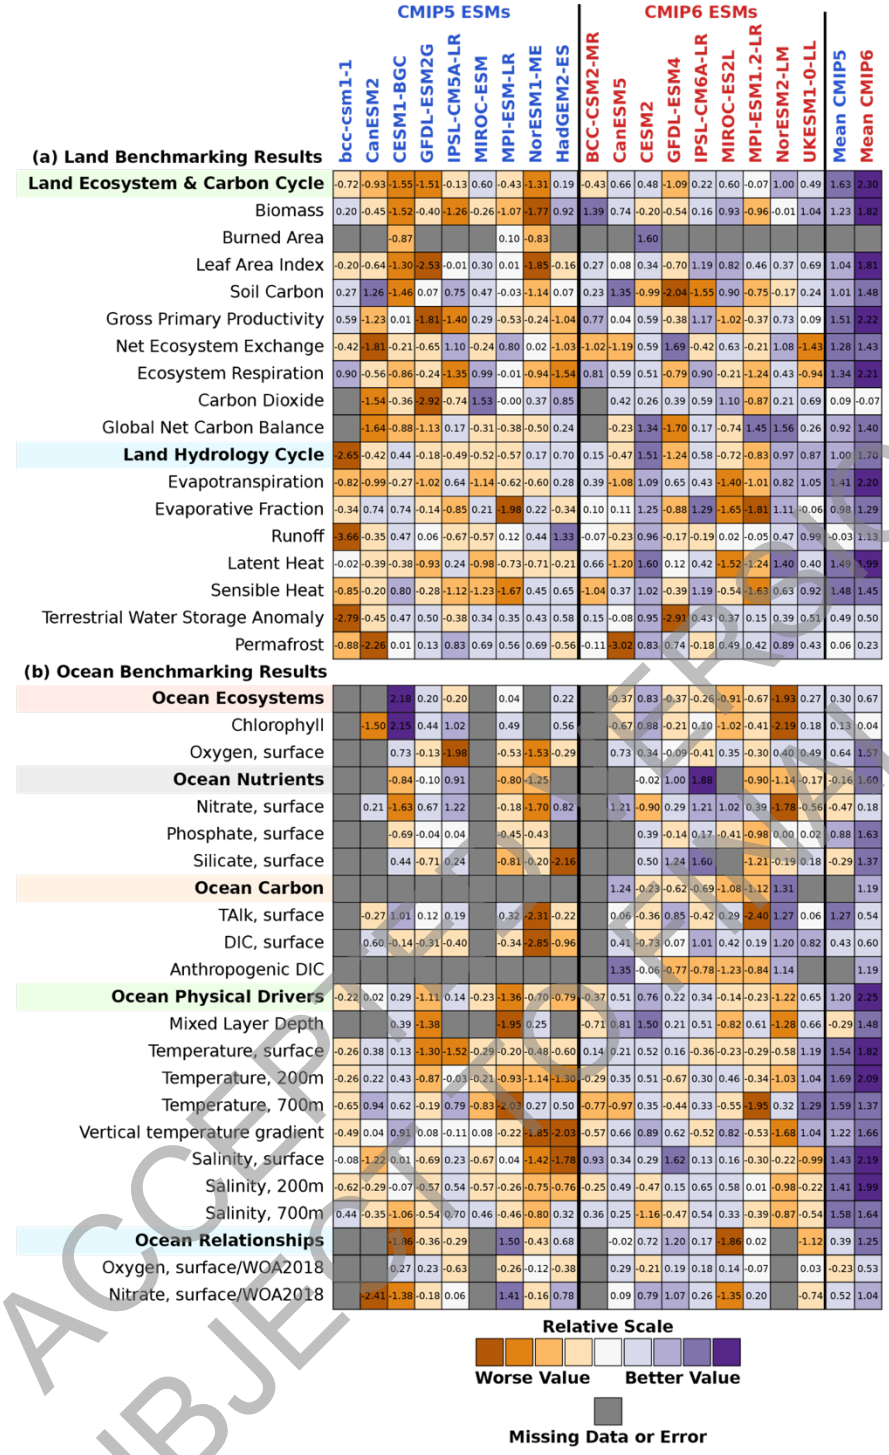


Figure 5.21: Spread of ocean acidification from the surface into the interior of ocean since pre-industrial times. (a) map showing the three transects used to create the cross sections shown in (b) and (c); vertical sections of the changes in (b) pH and (c) saturation state of aragonite (Ω_{arag}) between 1800–2002 due to anthropogenic CO_2 invasion (colour). Contour lines are their contemporary values in 2002. The red transect begins in the Nordic Seas and then follows the GO-SHIP lines A16 southward in the Atlantic Ocean, SR04 and S04P westward in the Southern Ocean, and P16 northward in the Pacific Ocean. The purple line follows the GO-SHIP line I09 southward in the Indian Ocean. The green line on the smaller inset crosses the Arctic Ocean from the Bering Strait to North Pole along 175°W and from the North Pole to the Fram Strait along 5°E (Lauvset et al., 2020). Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

Figure 5.22: Overview scores for CMIP5 (left hand side of table) and CMIP6 (right hand side of table) Earth system models (ESMs), for multiple benchmarks against different datasets. (a) Benchmarking of ESM land models, (b) benchmarking of ocean models. Scores are relative to other models within each benchmark row, with positive scores indicating a better agreement with observations. Models included are only those from institutions that participated in both CMIP5 and CMIP6 carbon cycle experiments, in order to trace changes from one ensemble to the next. CMIP5 models are labels in yellow and CMIP6 in green, with the multi-model ensemble means labelled in white. Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

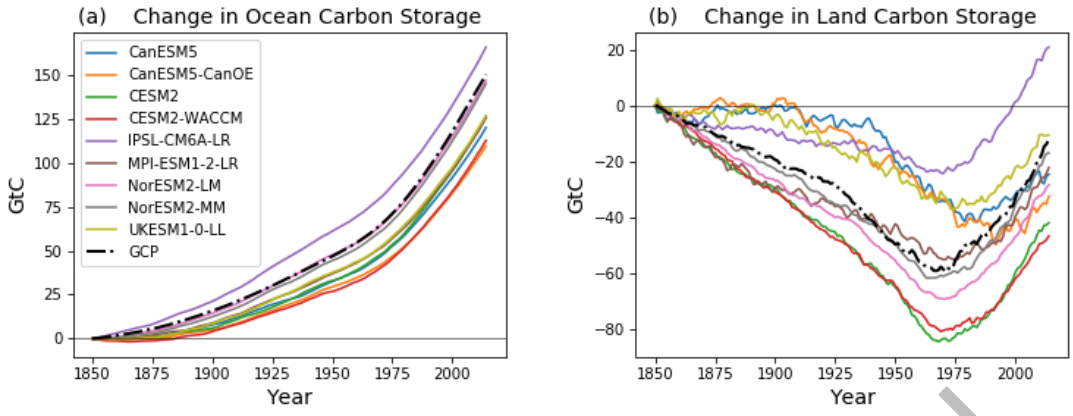

Figure 5.23: CMIP6 Earth system model (ESM) concentration-driven historical simulations for 1850 to 2014, compared to observation-based estimates from the global carbon project (GCP). Panel (a) cumulative ocean carbon uptake from 1850 (PgC); (b) cumulative land carbon uptake from 1850 (PgC). Only models that simulate both land and ocean carbon fluxes are shown here. Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

SUBJECT TO FINAL EDITS

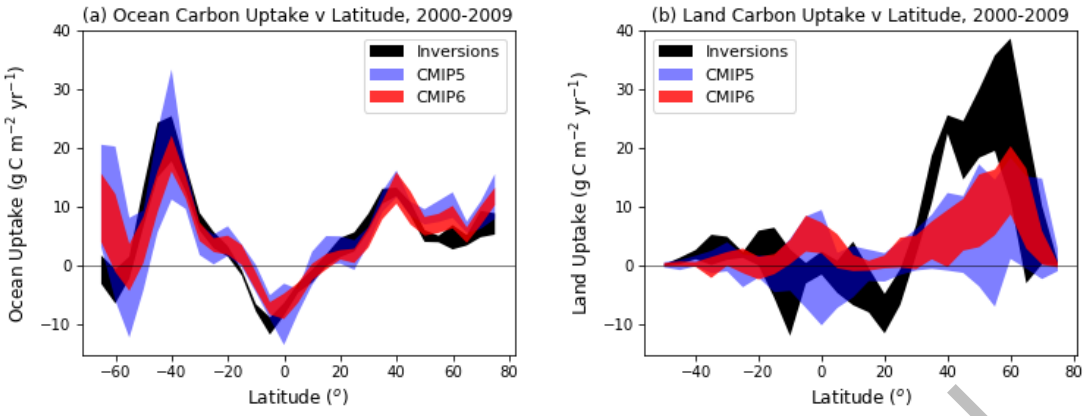

Figure 5.24: Comparison of modelled zonal distribution of contemporary carbon sinks against atmospheric inversion estimates for 2000–2009, (a) ocean carbon uptake; (b) net land uptake. Latitude runs from 90°S (i.e. –90°N) to 90°N. Positive uptake represents a carbon sink to ocean/land while negative uptake represents a carbon source. The land uptake is taken as Net Biome Productivity (NBP) and so includes net land-use change emissions. The bands show the mean ±1 standard deviation across the available inversions (black bands, 3 models), CMIP5 Earth system models (ESMs) (blue bands, 12 models for the ocean, 12 models for the land), and CMIP6 ESMs (red bands, 11 models for ocean, 10 models for land). Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

ACCEPTED VERSION
SUBJECT TO FINAL EDITS

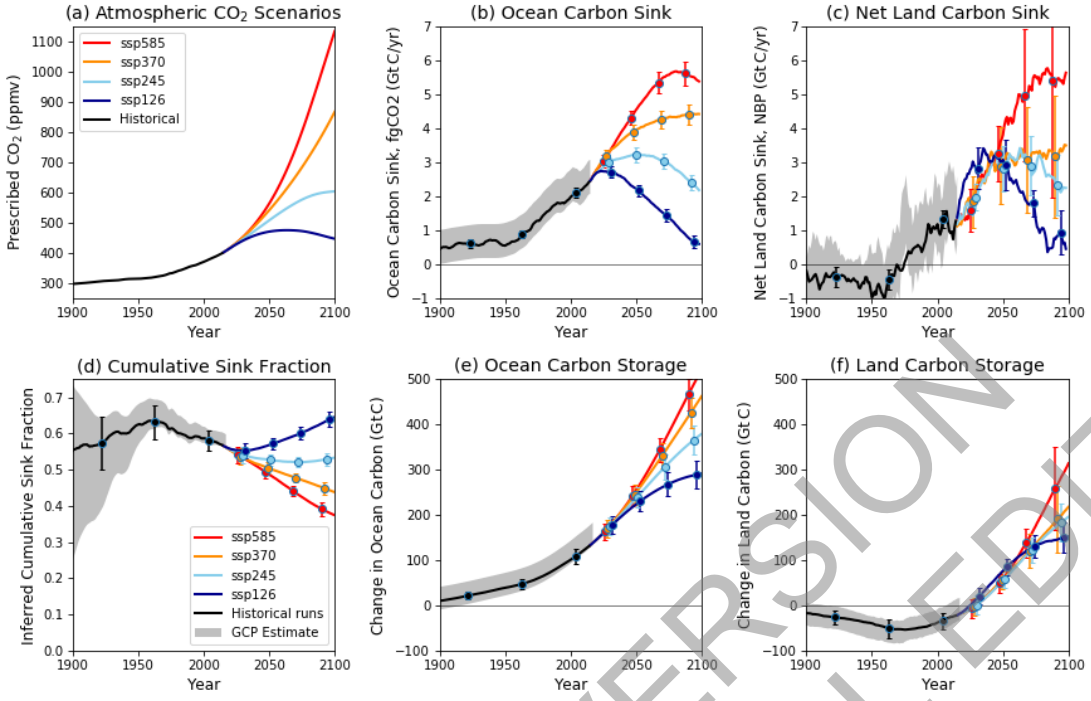

Figure 5.25: Modelled evolution of the global land and ocean carbon sinks for 1850 to 2100 in concentration-driven CMIP6 Earth system model (ESM) scenario runs (SSP1–2.6: blue; SSP2–4.5: skyblue; SSP3–7.0: yellow; SSP5–8.5: red): (a) prescribed atmospheric CO_2 concentrations; (b) 5-year running mean ocean carbon sink (GtC yr^{-1}); (c) 5-year running mean net land carbon sink (GtC yr^{-1}); (d) inferred cumulative sink fraction of emissions from 1850; (e) change in ocean carbon storage from 1850 (GtC); (f) change in land carbon storage from 1850 (GtC). Thick lines represent the ensemble mean of the listed ESM runs, and the error bars represents ± one standard deviation about that mean. The grey wedges represent estimates from the global carbon project (GCP), assuming uncertainties in the annual mean ocean and net land carbon sinks of 0.5 GtC yr^{-1} and 1 GtC yr^{-1} respectively, and uncertainties in the changes in carbon stores (ocean, land and cumulative total emissions) of 25 GtC. The net land carbon sink is taken as net biome productivity (NBP) and so includes any modelled net land-use change emissions. Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

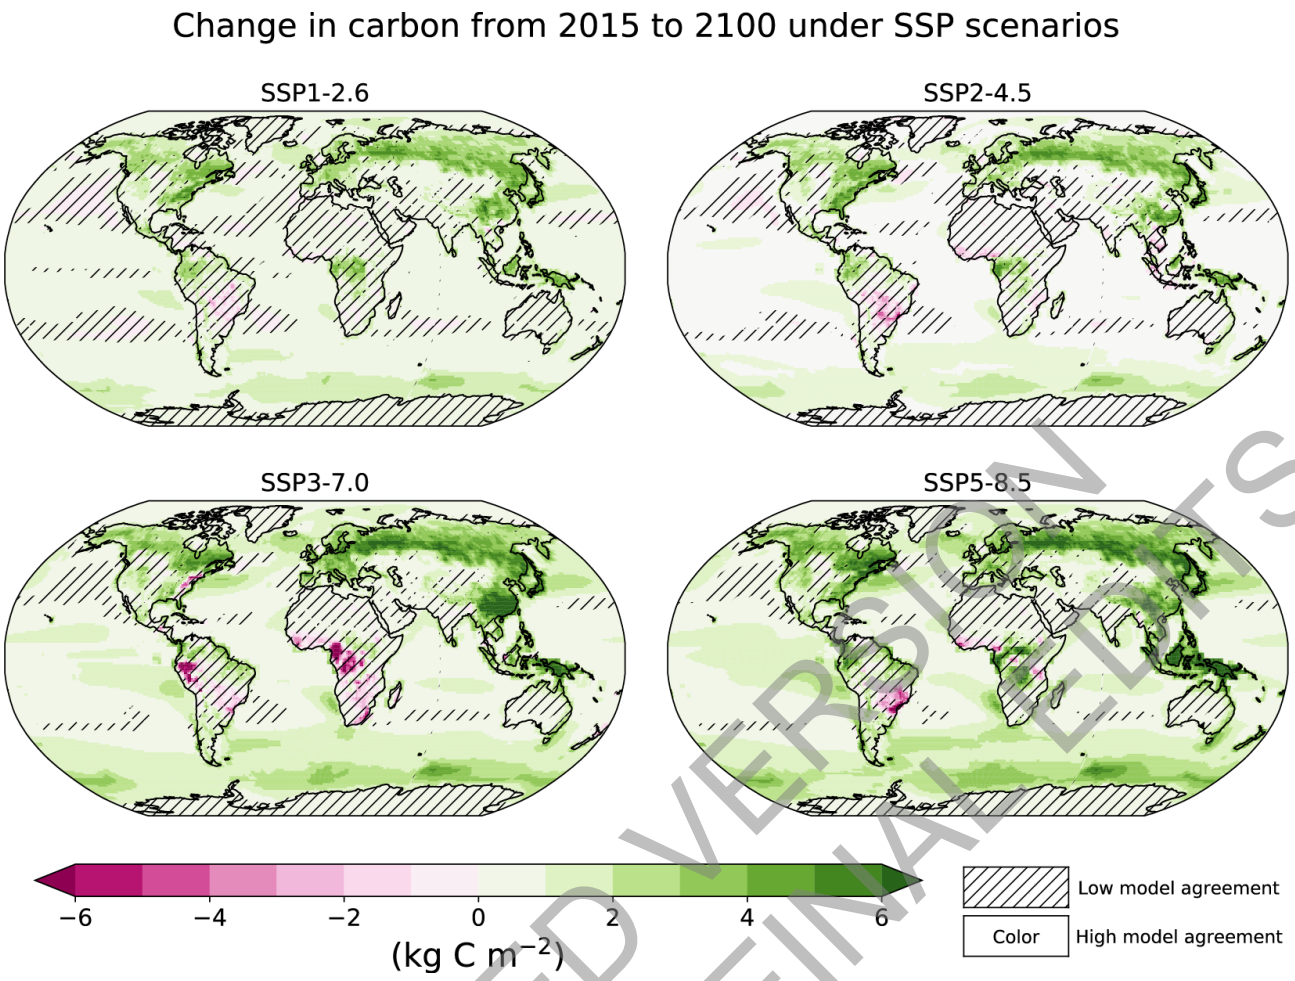

Figure 5.26: Maps of net carbon changes under four Shared Socioeconomic Pathway (SSP) scenarios, as evaluated from nine CMIP6 Earth system models. Uncertainty is represented using the simple approach (see Cross-Chapter Box Atlas.1 for more information): No overlay indicates regions with high model agreement, where ≥80% of models agree with the ensemble mean on the sign of change; diagonal lines indicate regions with low model agreement, where <80% of models agree with the ensemble mean on the sign of change. On land, this is calculated as the time integral of NBP, for the ocean it is the time-integral of air-sea CO_2 gas flux anomalies relative to the pre-industrial. Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

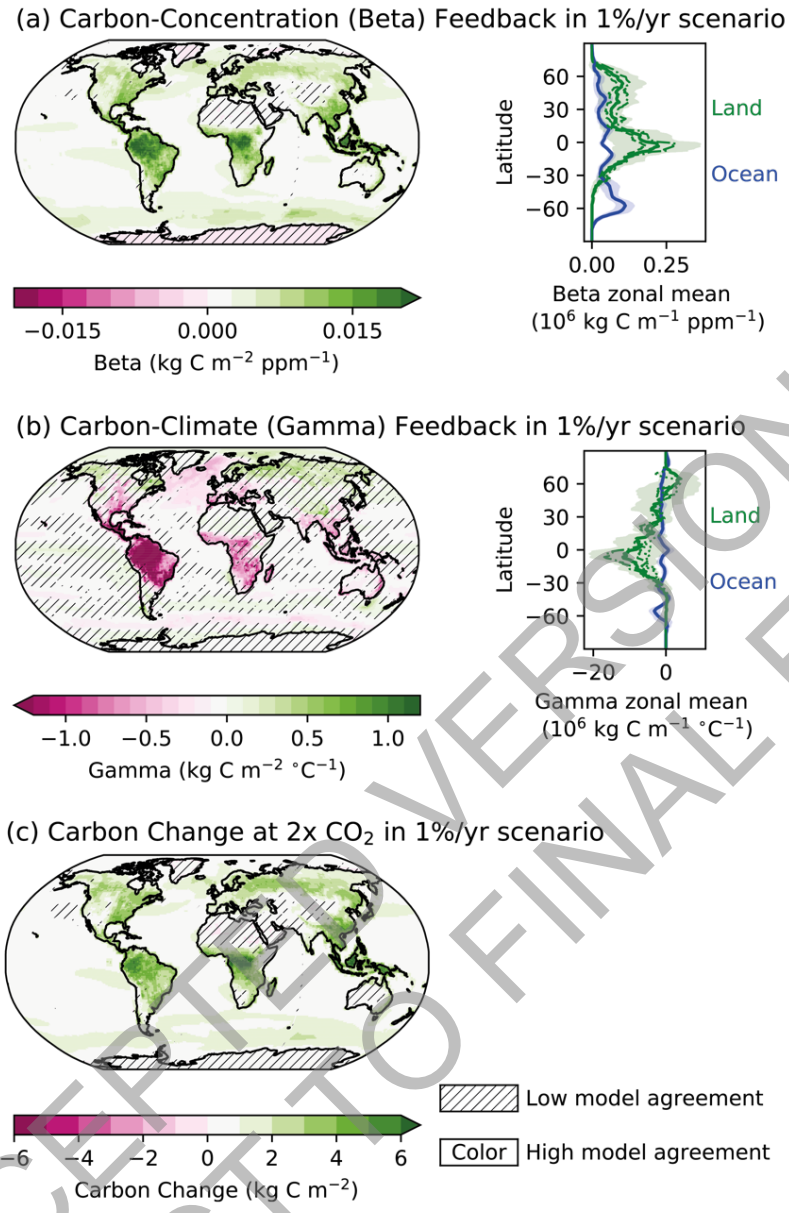

Figure 5.27: Maps of carbon-concentration and carbon-climate feedback terms, as well as net carbon changes under the idealised 1% per year CO_2 scenario, as evaluated from CMIP6 Earth system models (ESMs). Shown are the model means from nine CMIP6 ESMs. Uncertainty is represented using the simple approach (see Cross-Chapter Box Atlas.1 for more information): No overlay indicates regions with high model agreement, where ≥80% of models agree with the ensemble mean on the sign of change; diagonal lines indicate regions with low model agreement, where <80% of models agree with the ensemble mean on the sign of change. Also shown are zonal-mean latitude profiles of land (green) and ocean (blue) feedbacks. On the land, the zonal mean feedback for the mean of the ensemble of models that include nitrogen is shown as dashed lines, and carbon-only models as dash-dotted lines, and the carbon-climate feedback from one permafrost-carbon enabled ESM is shown as a dotted line carbon changes are calculated as the difference between carbon stocks at different times on land and for the ocean as the time integral of atmosphere-ocean CO_2 flux anomalies relative to the pre-industrial. The denominator for gamma here is the global mean surface air temperature. Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

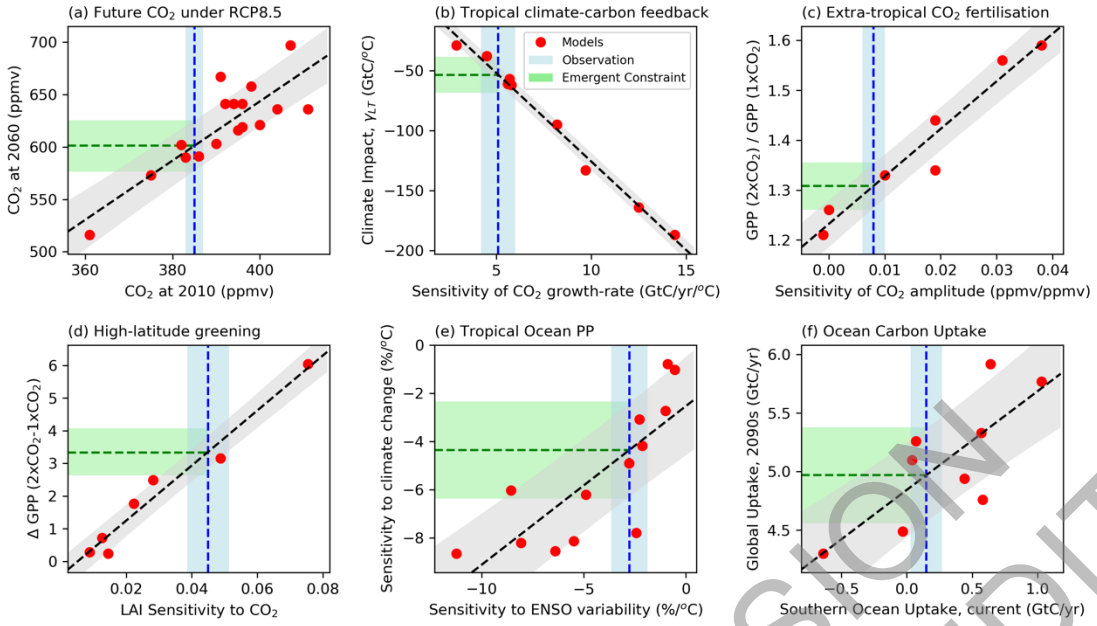

Figure 5.28: Examples of emergent constraints on the carbon cycle in Earth system models (ESMs), reproduced from previously published studies: (a) projected global mean atmospheric CO_2 concentration by 2060 under the RCP8.5 emissions scenario against the simulated CO_2 in 2010 (Friedlingstein et al., 2014; Hoffman et al., 2014); (b) sensitivity of tropical land carbon to warming (γ_{LT}) against the sensitivity of the atmospheric CO_2 growth-rate to tropical temperature variability (Cox et al., 2013; Wenzel et al., 2014); (c) sensitivity of extratropical (30°N–90°N) gross primary production to a doubling of atmospheric CO_2 against the sensitivity of the amplitude of the CO_2 seasonal cycle at Kumkahi, Hawaii to global atmospheric CO_2 concentration (Wenzel et al., 2016); (d) change in high-latitude (30°N–90°N) gross primary production versus trend in high-latitude leaf area index or 'greenness' (Winkler et al., 2019); (e) sensitivity of the primary production of the Tropical ocean to climate change versus its sensitivity to ENSO-driven temperature variability (Kwiatkowski et al., 2017); (f) global ocean carbon sink in the 2090s versus the current-day carbon sink in the Southern Ocean. In each case, a red-dot represents a single ESM projection, the grey bar represents the emergent relationship between the y-variable and the x-variable, the blue bar represents the observational estimate of the x-axis variable, and the green bar represents the resulting emergent constraint on the y-axis variable. The thicknesses represent ± one standard error in each case. Figure after Cox, (2019). Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

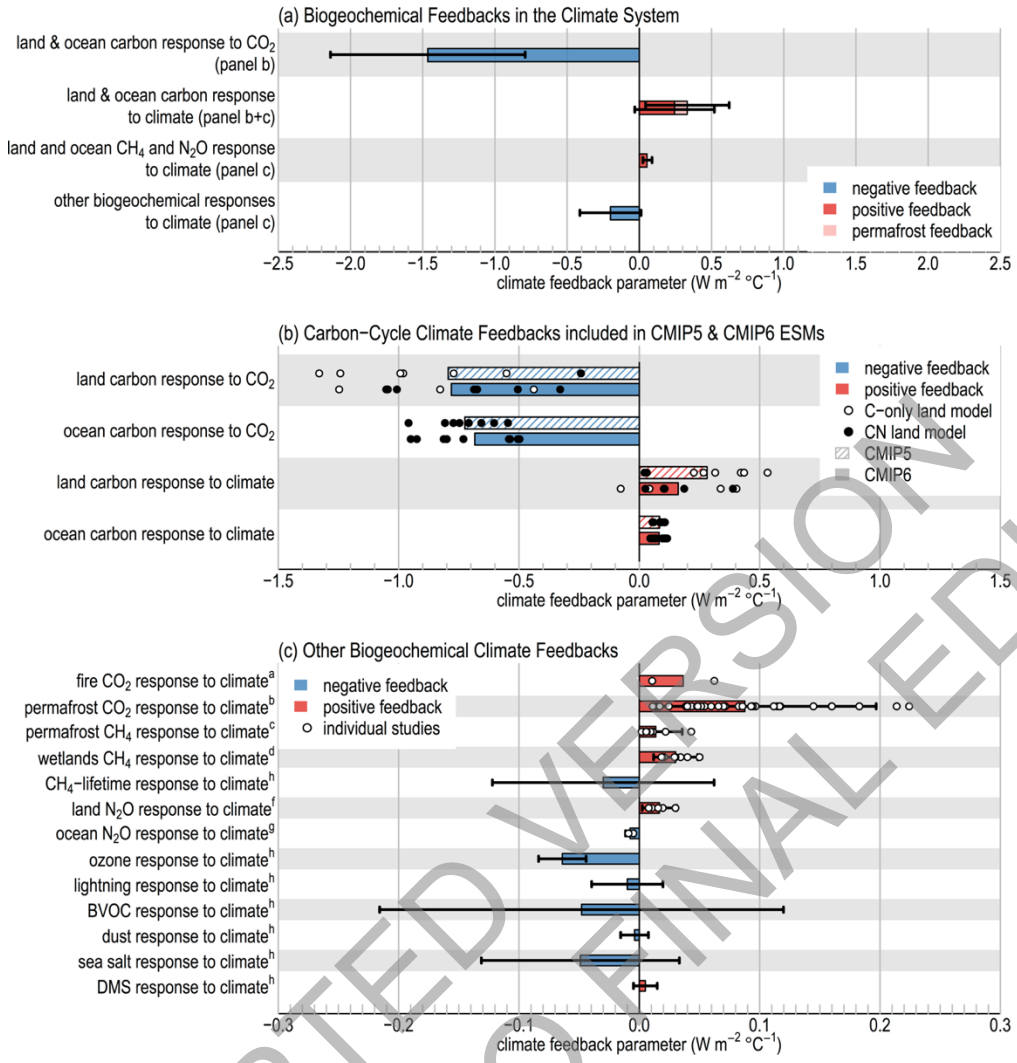

Figure 5.29: Estimates of the biogeochemical climate feedback parameter (α). The parameter α (W m^{-2} °C^{-1}) for a feedback variable x is defined as $\alpha_x = \frac{\partial N}{\partial x}\frac{dx}{dT}$ where $\frac{\partial N}{\partial x}$ is the change in TOA energy balance in response to a change in x induced by a change in surface temperature (T), as in Section 7.4.1.1. (a) Synthesis of biogeochemical feedbacks from panels (b) and (c). Red (blue) bars correspond to positive (negative) feedbacks increasing (decreasing) radiative forcing at the top of the atmosphere. Bars denote the mean and the error bar represents the 5–95th percentile range of the estimates; (b) carbon-cycle feedbacks as estimated by coupled carbon-cycle climate models in the CMIP5 (Arora et al., 2013) and CMIP6 (Arora et al., 2020) ensembles, where dots represent single model estimates, and filled (open) circles are those estimates which do (not) include the representation of a terrestrial nitrogen cycle; (c) Estimates of other biogeochemical feedback mechanisms based on various modelling studies. Dots represent single estimates, and coloured bars denote the mean of these estimates with no weighting being made regarding the likelihood of any single estimate, and error bars the 5–95th percentile range derived from these estimates. Results in panel (c) have been compiled from (a) Section 5.4.3.2 (Eliseev et al., 2014; Harrison et al., 2018); (b) Section 5.4.3.3 (Schneider von Deimling et al., 2012; Burke et al., 2013; Koven et al., 2015b, 2015a; MacDougall and Knutti, 2016; Burke et al., 2017; Gasser et al., 2018; Kleinen and Brovkin, 2018), where the estimates from Burke et al. have been constrained as assessed in their study (c) Section 5.4.7 (Schneider von Deimling et al., 2012; Koven et al., 2015b; Schneider von Deimling et al., 2015; Turetsky et al., 2020); (d) Section 5.4.7 (Arneth et al., 2010; Denisov et al., 2013; Shindell et al., 2013; Stocker et al., 2013; Zhang et al., 2017); (f) Section 5.4.7 (Xu-Ri et al., 2012; Zaehle, 2013; Stocker et al., 2013; Tian et al., 2019); (g) Section 5.4.7 (Martinez-Rey et al., 2015; Landolfi et al., 2017; Battaglia and Joos, 2018). (h) Section 6.3, Table 6.9 mean and the 5–95th percentile range the assessed feedback parameter. Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

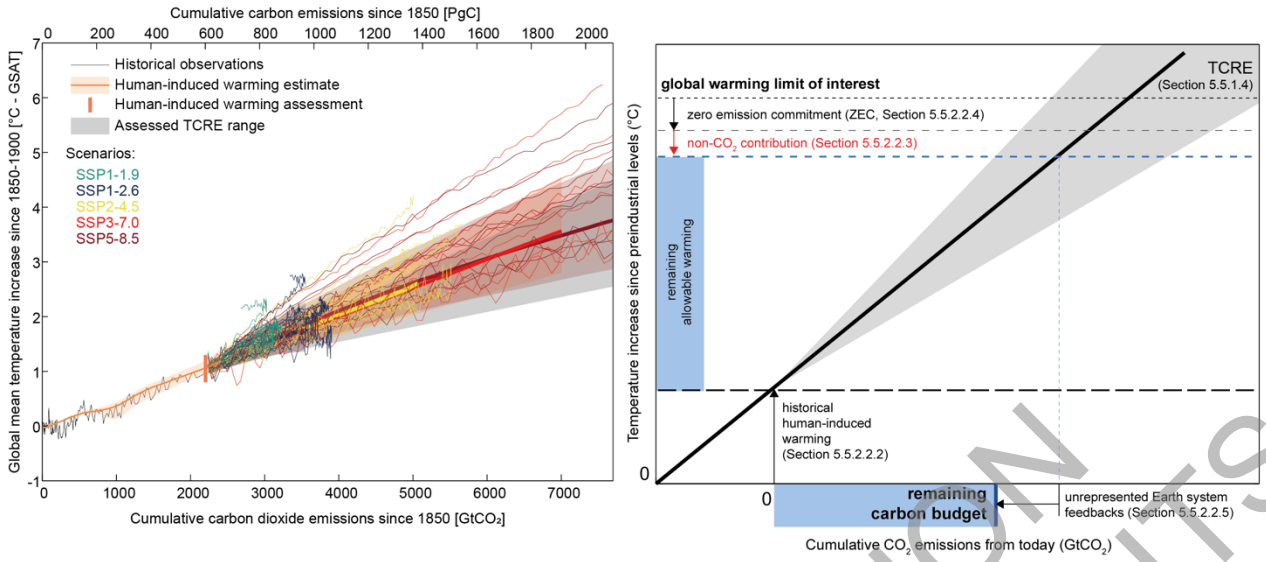

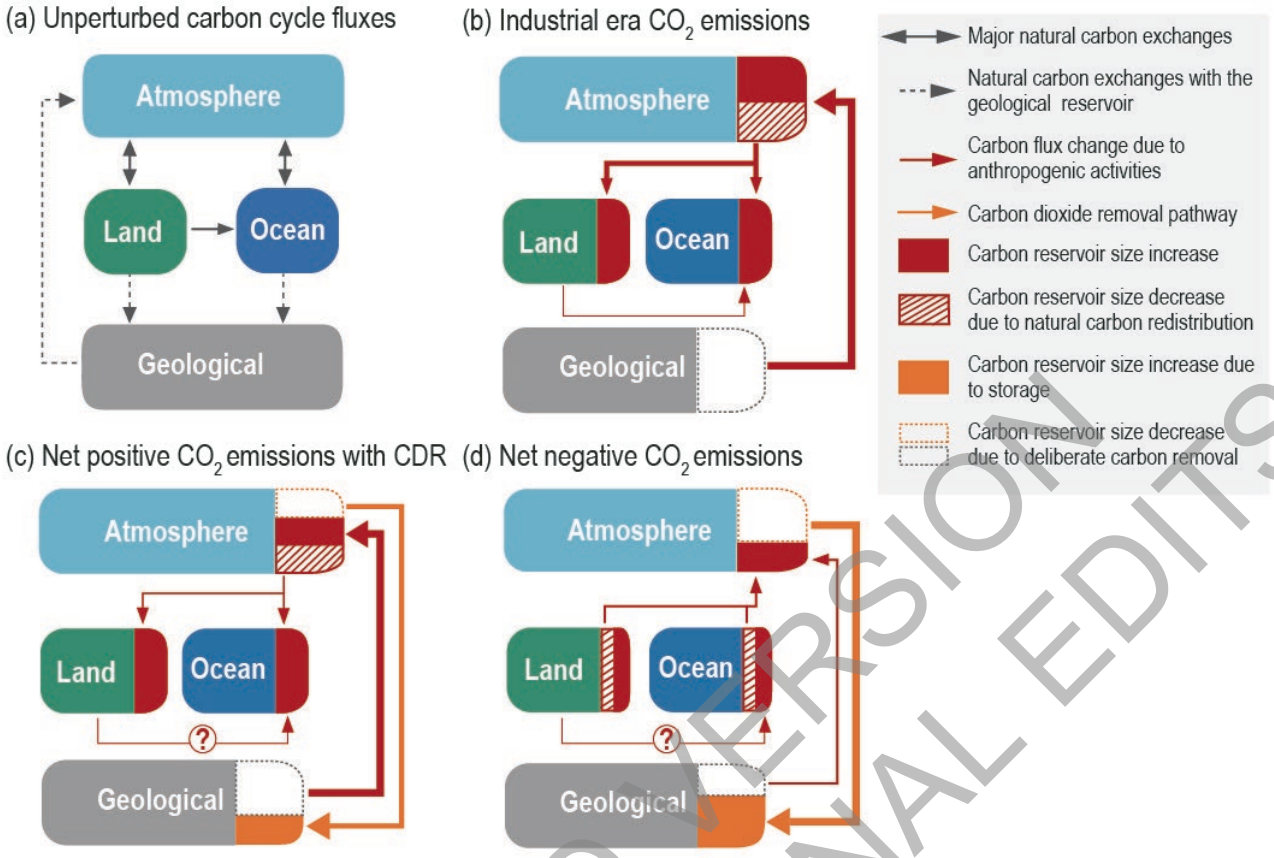

Figure 5.31: Illustration of relationship between cumulative emissions of carbon dioxide (CO_2) and global mean surface air temperature increase (left) and conceptual schematic of the assessment of the remaining carbon budget from its constituting components (right). Carbon budgets consistent with various levels of additional warming are provided in Table 5.8 and should not be read from the illustrations in either panel. Left-hand panel: Historical data (thin black line data) shows historical CO_2 emissions as reported in (Friedlingstein et al., 2020) together with the assessed global mean surface air temperature increase from 1850–1900 as assessed in Chapter 2 (Box 2.3, GSAT). The orange-brown range with its central line shows the estimated human-induced share of historical warming (Haustein et al., 2017). The vertical orange-brown line shows the assessed range of historical human-induced warming for the 2010–2019 period relative to 1850–1900 (Chapter 3). The grey cone shows the assessed range for the transient climate response to cumulative emissions of carbon dioxide (TCRE) assessed to fall *likely* in the 1.0–2.3 °C per 1000 PgC range (Section 5.5.1.4), starting from 2015. Thin coloured lines show CMIP6 simulations for the five scenarios of the AR6 core set (SSP1–1.9, green; SSP1–2.6, blue; SSP2–4.5, yellow; SSP3–7.0, red; SSP5–8.5, maroon), starting from 2015. Diagnosed carbon emissions (Arora et al., 2020) are complemented with estimated land-use change emissions for each respective scenario (Gidden et al., 2018). Coloured areas show the Chapter 4 assessed *likely* range of GSAT projections and thick coloured central lines the median estimate, for each respective scenario, relative to the original scenario emissions (Riahi et al., 2017; Gidden et al., 2018; Rogelj et al., 2018). Right-hand panel: schematic illustration of assessment of remaining carbon budget based on multiple lines of evidence. The remaining allowable warming is estimated by combining the global warming limit of interest with the assessed historical human induced warming (Section 5.5.2.2.2), the assessed future potential non-CO_2 warming contribution (Section 5.5.2.2.3) and the ZEC (Section 5.5.2.2.4). The remaining allowable warming (vertical blue bar) is subsequently combined with the assessed TCRE (Sections 5.5.1.4 and 5.5.2.2.1) and contribution of unrepresented Earth system feedbacks (Section 5.5.2.2.5) to provide an assessed estimate of the remaining carbon budget (horizontal blue bar, Table 5.8). Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Box 5.3, Figure 1: Schematic representation of carbon fluxes between atmosphere, land, ocean and geological reservoirs. Different system conditions are shown: (a) an unperturbed Earth system; and changes in carbon fluxes for (b) an Earth system perturbed by fossil-fuel CO_2 emissions, (c) an Earth system in which fossil-fuel CO_2 emissions are partially offset by CDR, (d) an Earth system in which CDR exceeds CO_2 emissions from fossil fuels ("net negative" CO_2 emissions). Carbon fluxes depicted in (a) (solid and dashed black lines) also occur in (b)-(d). The question mark in the land-to-ocean carbon flux perturbation in (c) and (d) indicates that the effect of CDR on this flux is unknown. Note that box sizes do not scale with the size of carbon reservoirs. Adapted from (Keller et al., 2018a). Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

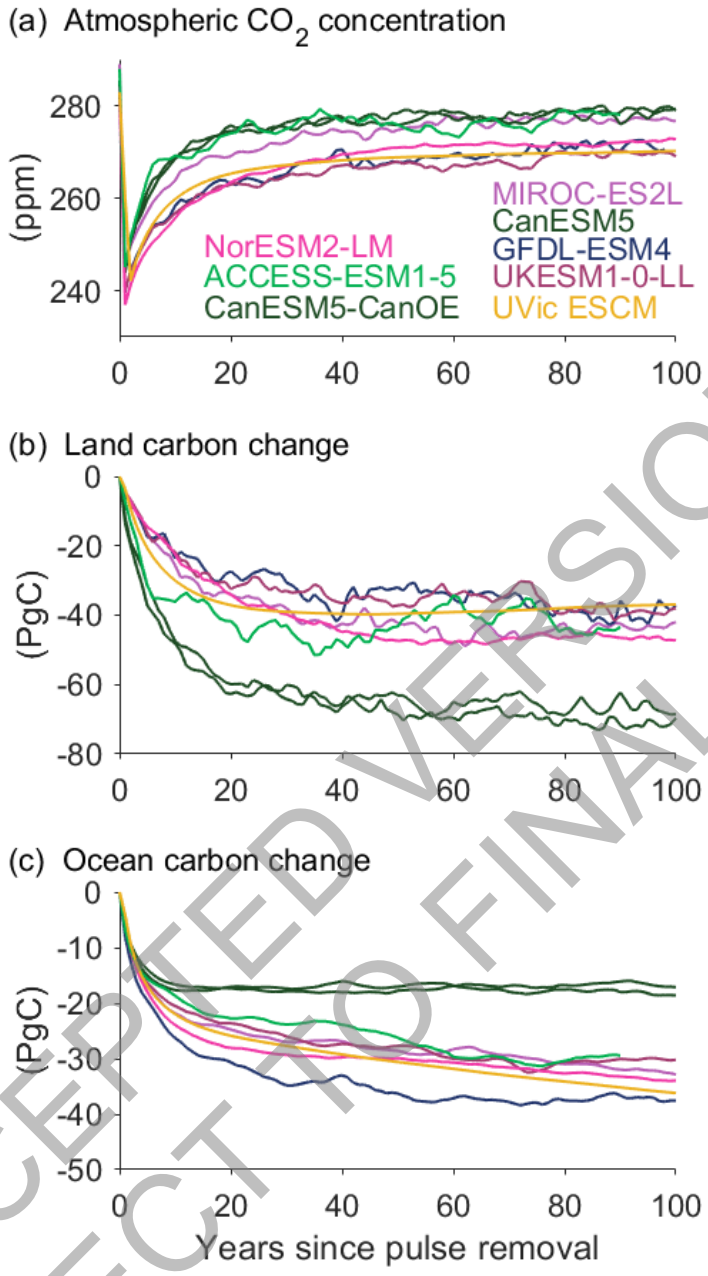

Figure 5.32: Carbon cycle response to instantaneous carbon dioxide (CO_2) removal from the atmosphere. (a) Atmospheric CO_2 concentration, (b) change in land carbon reservoir, (c) change in ocean carbon reservoir. Results are shown for simulations with seven CMIP6 Earth system models and the UVic ESCM model of intermediate complexity forced with 100 PgC instantaneously removed from the atmosphere. The 'pulse' removal is applied from a model state in equilibrium with a pre-industrial atmospheric CO_2 concentration (CDRMIP experiment CDR-pi-pulse; Keller et al., 2018b). Changes in land and ocean carbon reservoirs are calculated relative to a pre-industrial control simulation. Data for the UVic ESCM is from Zickfeld et al. (2021). Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

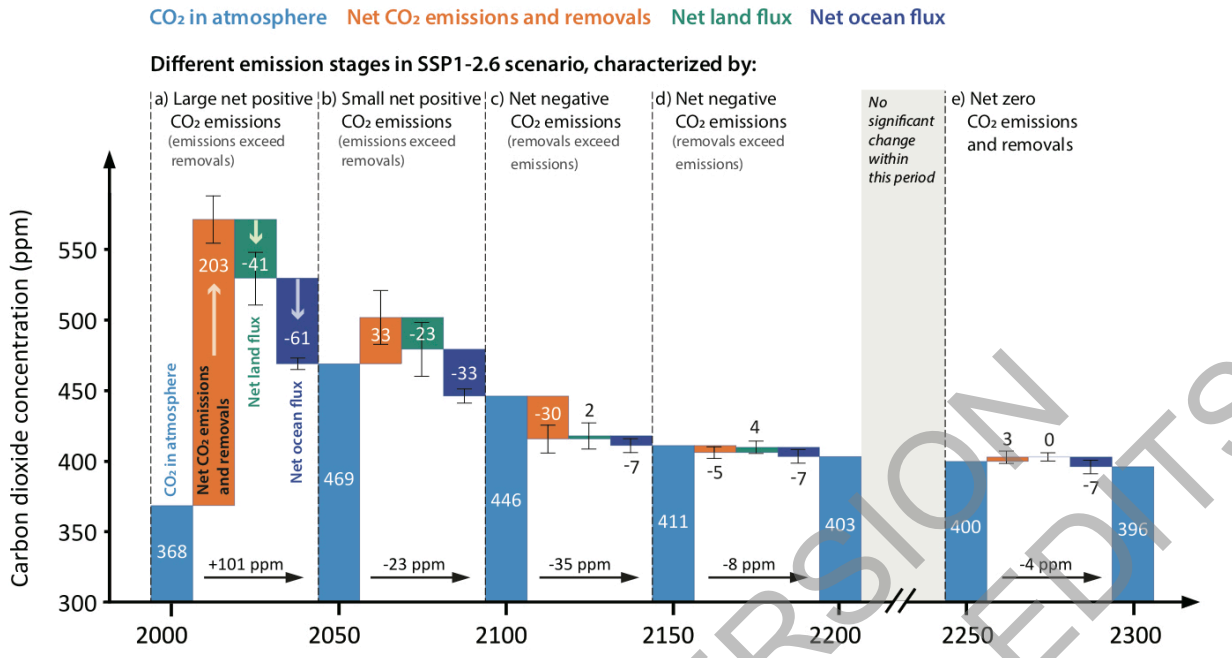

Figure 5.33: Carbon sink response in a scenario with net carbon dioxide (CO_2) removal from the atmosphere. Shown are CO_2 flux components from concentration-driven Earth system model simulations during different emission stages of SSP1–2.6 and its long-term extension. (a) Large net positive CO_2 emissions, (b) small net positive CO_2 emissions, (c) – (d) net negative CO_2 emissions, (e) net zero CO_2 emissions. Positive flux components act to raise the atmospheric CO_2 concentration, whereas negative components act to lower the CO_2 concentration. Net CO_2 emissions, land and ocean CO_2 fluxes represent the multi-model mean and standard deviation (error bar) of four ESMs (CanESM5, UKESM1, CESM2-WACCM, IPSL-CM6a-LR) and one EMIC (UVic ESCM; (Mengis et al., 2020)). Net CO_2 emissions are calculated from concentration-driven Earth system model simulations as the residual from the rate of increase in atmospheric CO_2 and land and ocean CO_2 fluxes. Fluxes are accumulated over each 50-year period and converted to concentration units (ppm). Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

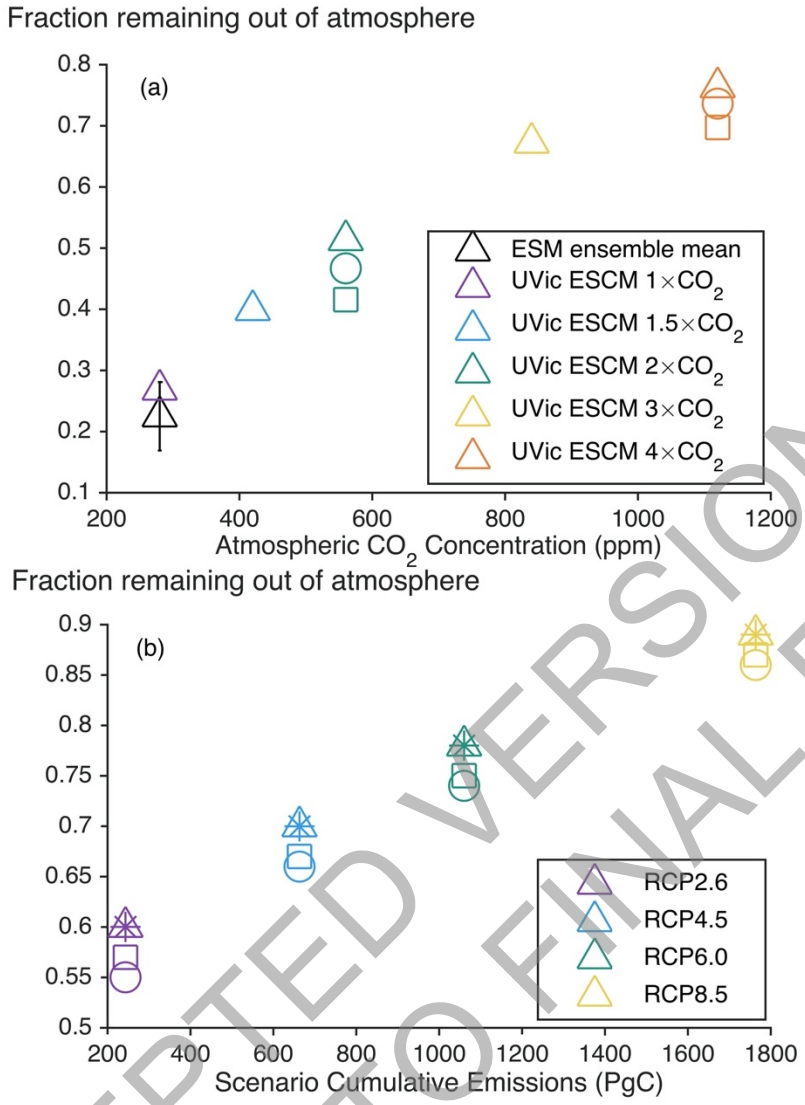

Figure 5.34: Removal effectiveness of carbon dioxide removal (CDR). (a) Fraction of CO_2 remaining out of the atmosphere for idealised model simulations with CDR applied instantly (pulse removals) from climate states in equilibrium with different atmospheric CO_2 concentration levels (1 to 4 times the pre-industrial atmospheric CO_2 concentration; shown on the horizontal axis). The fraction is calculated 100 years after pulse removal. The black triangle and error bar indicate the multi-model mean and standard deviation for the seven Earth system models shown in Figure 5.32 forced with a 100 PgC pulse removal. Other symbols illustrate results with the UVic ESCM model of intermediate complexity for different magnitudes of pulse removals (triangles: –100 PgC; circles: –500 PgC; squares: –1000 PgC). Data for the UVic ESCM is from (Zickfeld et al., 2021). (b) Perturbation airborne fraction (see text for definition) for model simulations where CDR is applied from four RCPs (shown on the horizontal axis in terms of their cumulative CO_2 emissions during 2020–2099). Symbols indicate results for four CDR scenarios, which differ in terms of the magnitude and rate of CDR (see Jones et al. (2016b) for details). Results are based on simulations with the Hadley Centre Simple Climate-Carbon Model and are shown for the year 2100. Data from Jones et al. (2016b). Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

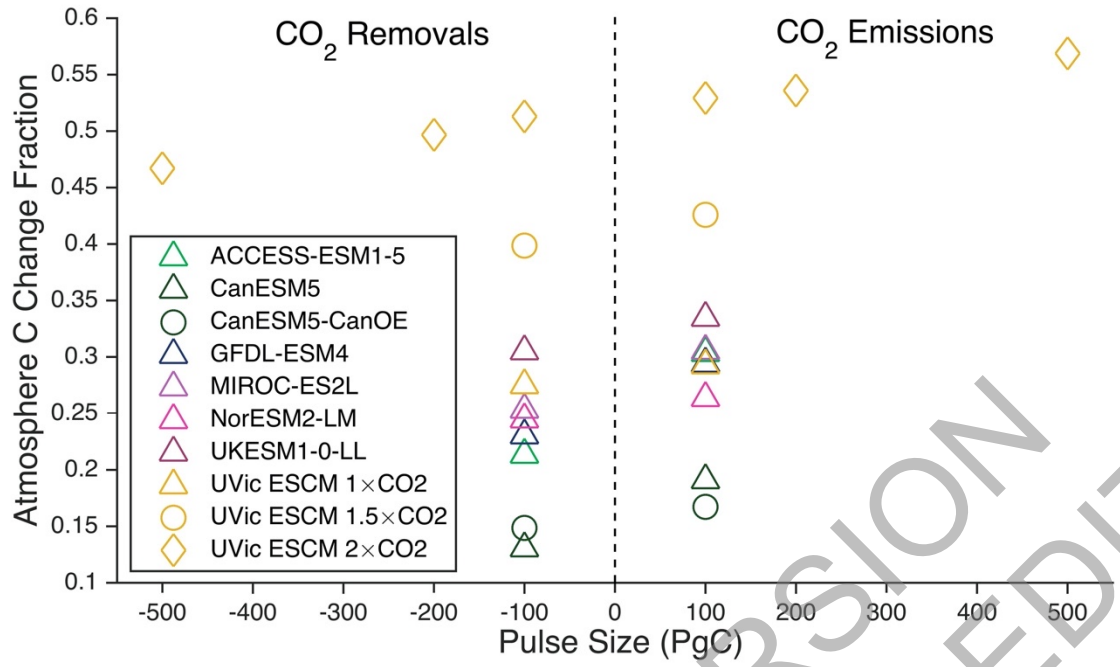

Figure 5.35: Asymmetry in the atmospheric carbon dioxide (CO_2) response to CO_2 emissions and removals. Shown are the fractions of total CO_2 emissions remaining in the atmosphere (right-hand side) and CO_2 removals remaining out of the atmosphere (left-hand side) 80–100 after a pulse emission/removal. Triangles and green circles denote results for seven Earth system models (ESMs) and the UVic ESCM model of intermediate complexity forced with ±100 PgC pulses applied from a pre-industrial state ($1\times CO_2$) (CDRMIP experiment CDR-pi-pulse; Keller et al. (2018b)). Yellow circles and diamonds indicate UVic ESCM results for CO_2 emissions/removals applied at 1.5 times ($1.5\times CO_2$) and 2 times ($2\times CO_2$) the pre-industrial CO_2 concentration, respectively. Pulses applied from a $2\times CO_2$ state span the magnitude ±100 PgC to ±500 PgC. UVic ESCM data is from (Zickfeld et al., 2021). Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

ACCEPTED VERSION SUBJECT TO FINAL EDITS

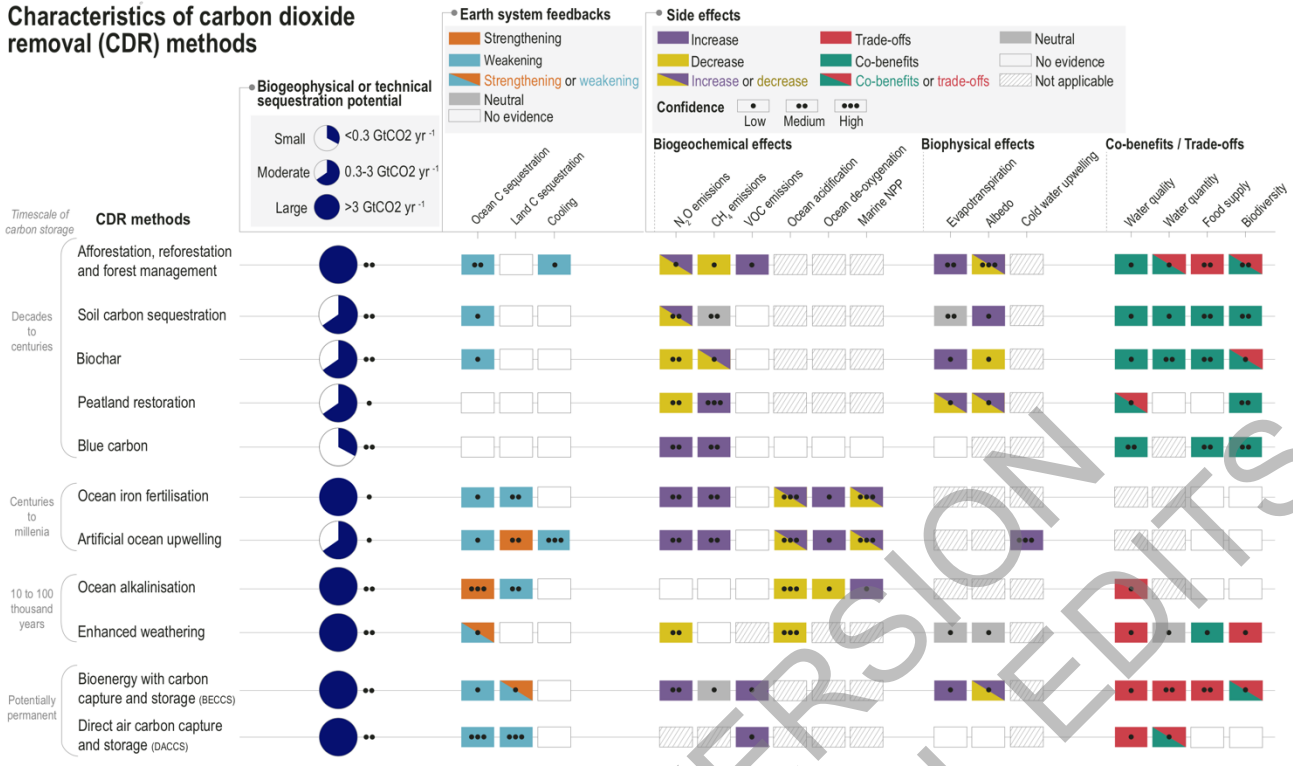

Figure 5.36: Characteristics of carbon dioxide removal (CDR) methods, ordered according to the time scale of carbon storage. The first column shows biogeophysical (for open-ocean methods) or technical (for all other methods) sequestration potentials (i.e. the sequestration potentials constrained by biological, geophysical, geochemical limits and thermodynamics and, for technical potentials, availability of technologies and practices; technical potentials for some methods also consider social or environmental factors if these represent strong barriers for deployment; see Glossary), classified into low (< 0.3 $GtCO_2$ yr^{-1}), moderate (0.3–3 $GtCO_2$ yr^{-1}) and large (>3 $GtCO_2$ yr^{-1}) (details underlying this classification are provided in Supplementary Materials Table 5.SM.5). The other columns show Earth system feedbacks that deployment of a given CDR method would have on carbon sequestration and climate, along with biogeochemical, biophysical, and other side effects of a given method. Earth system feedbacks do not include the direct effect of CO_2 sequestration on atmospheric CO_2, only secondary effects. For Earth system feedbacks, the colours indicate whether the feedbacks strengthen or weaken carbon sequestration and the climate cooling effect of a given CDR method. For biogeochemical and biophysical side effects the colours indicate whether the deployment of a CDR method increases or decreases the magnitude of the effect, whereas for co-benefits and trade-offs the colour indicates whether deployment of a CDR method results in beneficial (co-benefits) or adverse side-effects (trade-offs) for water quality and quantity, food production and biodiversity. The details and references underlying the Earth system feedback and side-effect assessment are provided in Supplementary Materials Table 5.SM.4. Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

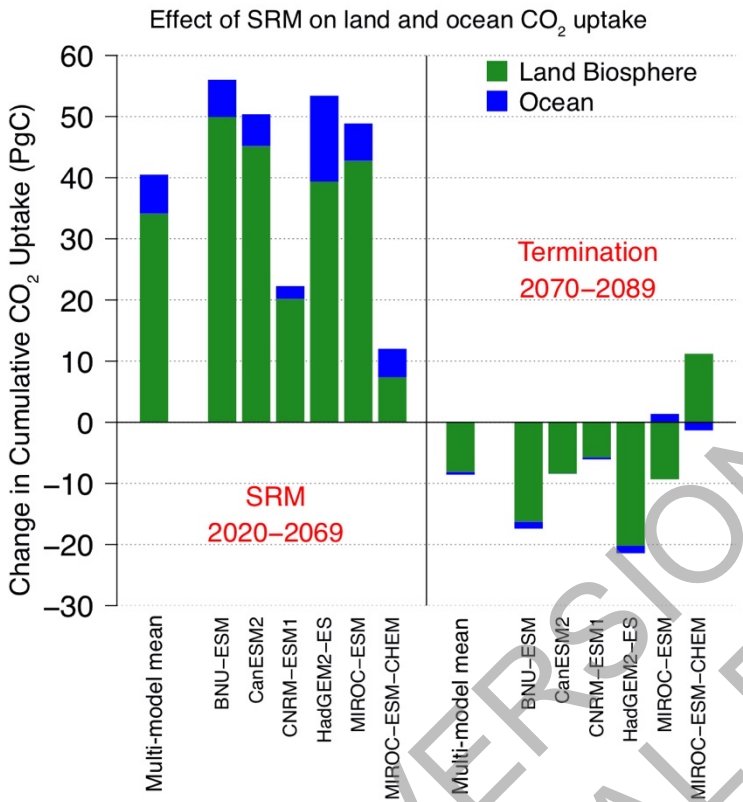
ACCEPTED VERSION SUBJECT TO FINAL EDITS



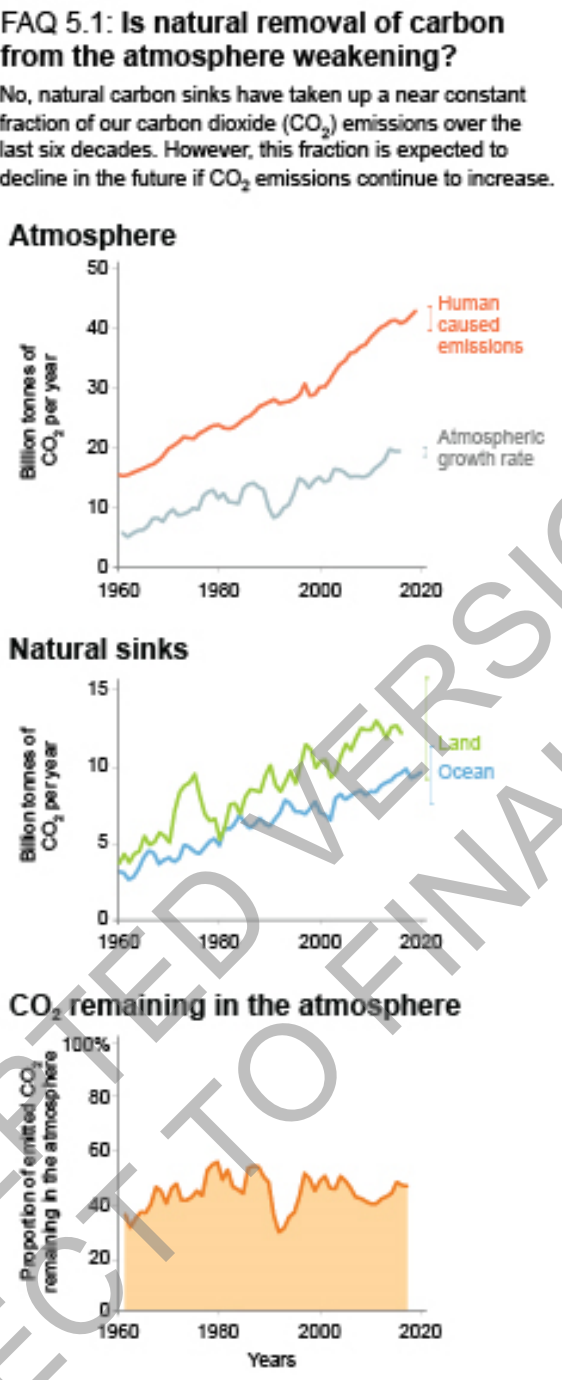


Figure 5.37: Cumulative carbon dioxide (CO_2) uptake by land and ocean carbon sinks in response to stratospheric sulfur dioxide (SO_2) injection. Results are shown for a scenario with 50-year (2020−2069) continuous stratospheric SO_2 injection at a rate of 5 Tg per year appplied to a RCP4.5 baseline scenario (GeoMIP experiment G4: Kravitz et al., (2011)), followed by termination in year 2070. Anomalies are shown relative to RCP4.5 for the multimodel ensemble mean and for each of six ESMs over the 50-year period of stratospheric SO_2 injection (left), and over 20 years after termination of SO_2 injection (right). Adapted from Plazzotta et al. (2019). Further details on data sources and processing are available in the chapter data table (Table 5.SM.6).

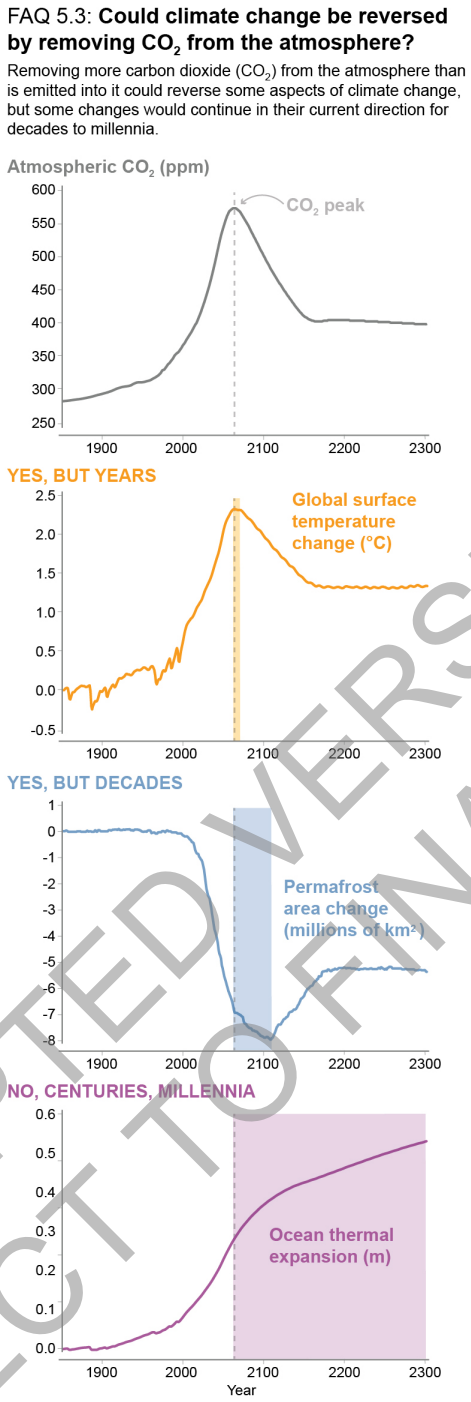
FAQ 5.1, Figure 1: Atmospheric CO2 and natural carbon sinks. (Top) Global emissions of CO2 from human activities and the growth rate of CO2 in the atmosphere, (middle) the net land and ocean CO2 removal ("natural sinks"), as well as (bottom) the fraction of CO2 emitted by human activities remaining in atmosphere from 1960 to 2019. Lines are the five years running mean, error-bars denote the uncertainty of the mean estimate. See Table 5.SM.6 for more information on the data underlying this figure.

ACCEPTED VERSION SUBJECT TO FINAL EDITS

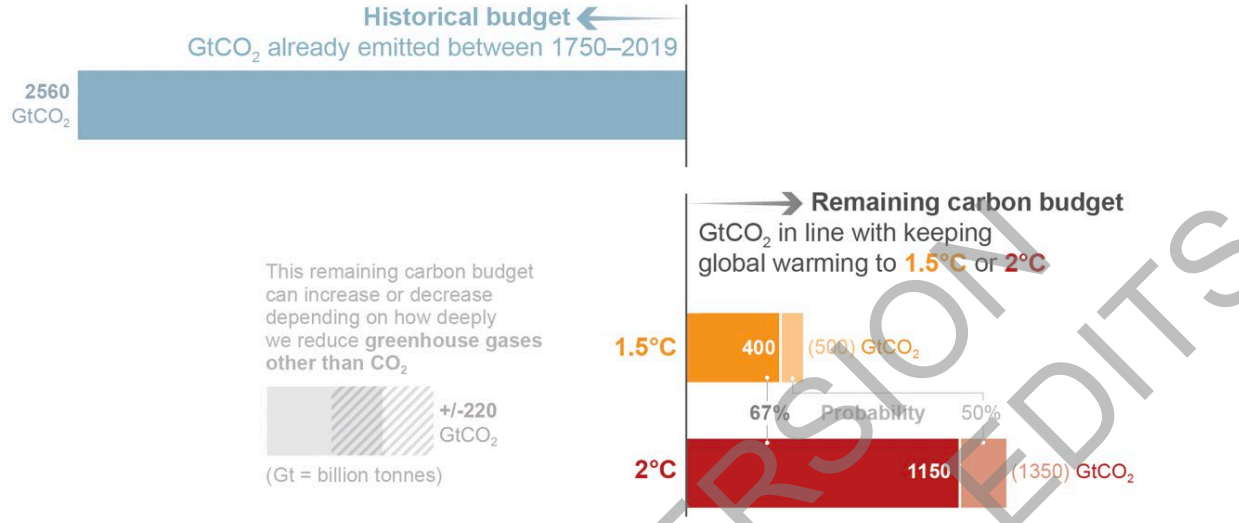


FAQ5.2: **Can thawing permafrost substantially increase global temperatures?**

The thawing of frozen ground in the Arcrtic will release carbon that will amplify global warming but this will not lead to runaway warming.

FAQ 5.2, Figure 1: The Arctic permafrost is a big pool of carbon that is sensitive to climate change. (left) Quantity of carbon stored in the permafrost, to 3 m depth (NCSCDv2 dataset) and (right) area of permafrost vulnerable to abrupt thaw (Circumpolar Thermokarst Landscapes dataset).

ACCEPTED VERSION SUBJECT TO FINAL EDITS



ACCEPTED VERSION SUBJECT TO FINAL EDITS

FAQ 5.3, Figure 1: Changes in aspects of climate change in response to a peak and decline in the atmospheric CO_2 concentration (top panel). The vertical grey dashed line indicates the time of peak CO_2 concentration in all panels. It is shown that the reversal of global surface warming lags the decrease in the atmospheric CO_2 concentration by a few years, the reversal of permafrost area decline lags the decrease in atmospheric CO_2 by decades, and ocean thermal expansion continues for several centuries. Note that the quantitative information in the figure (i.e., numbers on vertical axes) is not to be emphasized as it results from simulations with just one model and will be different for other models. The qualitative behaviour, however, can be expected to be largely model independent.

1

FAQ 5.4: **What are Carbon Budgets?**

The term carbon budget is used in several ways. Most often the term refers to the total net amount of carbon dioxide (CO_2) that can still be emitted by human activities while limiting global warming to a specified level.

2

3 **FAQ 5.4, Figure 1: Various types of carbon budgets.** Historical cumulative CO_2 emissions determine to a large
4 degree how much the world has warmed to date, while the remaining carbon budget
5 indicates how much CO_2 could still be emitted while keeping warming below specific
6 temperature thresholds. Several factors limit the precision with which the remaining
7 carbon budget can be estimated, and estimates therefore need to specify the probability
8 with which they aim at limiting warming to the intended target level (e.g., limiting
9 warming to 1.5°C with a 67% probability).

5.SM.1 Assessment of recent advances in observational and modelling methodologies

Since AR5 three major advances have had a decisive impact on the levels of confidence of the trends and the variability of both air-sea fluxes of CO_2 and its storage in the ocean interior. These are (i) the new observations and observational-based products for decadal variability in ocean uptake fluxes and ocean storage, (ii) the observational-based product changes in amplitude of the seasonal cycle of surface ocean pCO_2 (the partial pressure of CO_2 expressed in μatm) in response to changing ocean carbonate chemistry, and (iii) spatially-resolved pCO_2 seasonal climatologies for the global coastal ocean (Gruber et al., 2019a; (Rödenbeck et al., 2015; Landschützer et al., 2016, 2018); Laruelle et al., 2017). These advances were made possible by the simultaneous global coordination of observations and data quality control through the surface ocean CO_2 atlas (SOCAT) and Lamont-Doherty Earth observatory (LDEO) as well as the rapid adoption of a large variety of interpolation techniques for the surface layer and their inter-comparison to constrain uncertainties and biases (Rödenbeck et al., 2015; Bakker et al., 2016; Landschützer et al., 2016; McKinley et al., 2017; Gregor et al., 2019; Gruber et al., 2019b).

Advances in the multiple methods of interpolating surface ocean pCO_2 observations provide a *medium to high confidence* in the air-sea fluxes of CO_2 over most of the ocean (Rödenbeck et al., 2015; Landschützer et al., 2016; Gregor et al., 2019). However, there is *low confidence* in those fluxes for important regions such as the Southern Ocean, the Arctic, South Pacific as well as coastal oceans (Laruelle et al., 2017; Gregor et al., 2019; Gruber et al., 2019c); while these regions remain temporally and spatially under sampled the development and deployment of carbon and biogeochemically enabled Argo autonomous floats is starting to close those gaps (Williams et al., 2017; Gray et al., 2018; Claustre et al., 2020).

Similarly, for anthropogenic carbon storage in the ocean interior (i.e. below the mixed layer) the global ocean ship-based hydrographic investigations programme (GO-SHIP) coupled to the global ocean data analysis project for carbon (GLODAPv2) were central to supporting the advances in characterising changes to the storage in the ocean interior by generating a new consistent, quality-controlled, global dataset, allowing the decadal variability in ocean carbon storage to be quantified (Lauvset et al., 2016; Olsen et al., 2016; Clement and Gruber, 2018; Gruber et al., 2019b). There is *high confidence* that a significant advance since AR5 and SROCC is the improved characterization of the variability of the ocean CO_2 storage trends in space and time, which has notable decadal and regional scale variability (Tanhua et al., 2017; Gruber et al., 2019b) (SROCC Chapters 3 and 5).

Since it is also unequivocal that anthropogenic CO_2 taken up from the atmosphere into the ocean surface layer is further transported into the ocean interior through ocean ventilation processes including vertical mixing, diffusion, subduction and meridional overturning circulations (Sallée et al., 2012; Nakano et al., 2015; Bopp et al., 2015; Iudicone et al., 2016; Toyama et al., 2017), the trends as well as the spatial and temporal variability were assessed in an integrated way for both the air-sea flux and storage of anthropogenic CO_2.

5.SM.2 SeaFlux method: a 4 step methodological approach to address the first order inconsistencies between the ocean six (6) CO_2 flux observational based products used in Chapter 5 (5.2.3.1)

Contributors: Amanda Fay and Luke Gregor

Methods

The SeaFlux method is based on six published and widely used observation-based products of surface ocean partial pressure (of CO_2 (pCO_2) and spans years 1988–2018 (Gregor and Fay, 2021). These six include three neural network derived products (MPI-SOMFFN, CMEMS-FFNN, NIES-FNN), a mixed layer scheme product (JENA-MLS), a multiple linear regression (JMA-MLR), and a machine learning ensemble (CSIR-ML6) (Supplementary Materials Table 5.SM.1). These products are included as they have been regularly updated to extend their time period and incorporate additional data that comes with each annual release of the SOCAT database.

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Surface pCO_2 observations play a key role in constraining the global ocean carbon sink. This is because variations in surface ocean pCO_2 is the driving force governing the exchange of CO_2 across the air-sea interface, which is commonly described through a bulk formula (Garbe et al., 2014; Wanninkhof, 2014):

$$\text{Flux} = k_w \cdot sol \cdot (pCO_2 - pCO_2^{atm}) \cdot (1 - ice) \quad (1)$$

where k_w is the gas transfer velocity, *sol* is the solubility of CO_2 in seawater, in units mol m^{-3} μatm^{-1}, pCO_2 is the partial pressure of surface ocean CO_2 in µatm, and pCO^{atm} in units of µatm represents the partial pressure of atmospheric CO_2 in the marine boundary layer. Finally, to account for the seasonal ice cover in high latitudes the fluxes are weighted by 1 minus the ice fraction (*ice*), *i.e.* the open ocean fraction.

All of these methods provide full three-dimensional fields (latitude, longitude, time) of the sea surface partial pressure of CO_2 (pCO_2) and the air-sea CO_2 flux. In their original form each product may utilise different choices for the inputs to Equation 1. In this work recompute the fluxes using the following inputs to the bulk parameterization approach Equation 1: k_w is the gas transfer velocity, *sol* is the solubility of CO_2 in seawater, in units mol m^{-3} μatm^{-1}, calculated using the formulation by Weiss, (1974), EN4 salinity (Good et al., 2013), Operational Sea Surface Temperature and Sea Ice Analysis (OSTIA) sea surface temperature (Good et al., 2020), and European Centre for Medium- Range Weather Forecasts (ECMWF) ERA5 sea level pressure (Hersbach et al., 2020); *ice* is the sea ice fraction from OSTIA (Good et al., 2020); pCO_2 is the partial pressure of oceanic CO_2 in µatm for each observation-based product after filling, and pCO_2^{atm} is the dry air mixing ratio of atmospheric CO_2 (xCO_2) from the ESRL surface marine boundary layer CO_2 product available at https://www.esrl.noaa.gov/gmd/ccgg/mbl/data.php (Dlugokencky and Tans, 2020) multiplied by ERA5 sea level pressure (Hersbach et al., 2020) at monthly resolution, and applying the water vapor correction according to Dickson et al. (2007).

Flux is defined positive upward, that is CO_2 release from the ocean into the atmosphere is positive, and uptake by the ocean is negative. In the following sections we discuss the three steps that have the greatest impact on the inconsistencies between unadjusted flux calculations in the six pCO_2 products and the approach that we utilise for the SeaFlux ensemble product.

Step 1: Area filling

Machine learning methods aim to maximise the utility of the existing in situ observations by extrapolation using various proxy variables for processes influencing changes in ocean pCO_2. Extrapolation with these independently observed variables is possible due to the nonlinear relationship between pCO_2 in the surface ocean and the proxies that drive these changes.

However, not all of the proxy variables have complete global ocean coverage for all months, so the resulting pCO_2 products are limited by the extent of the proxy variables. Additionally, in coastal regions there is the potential that different relationships of pCO_2 are expected than in the open ocean, thus limiting the extrapolations. In contrast, the mixed layer scheme (utilised by the JENA-MLS product) does not suffer from such missing areas but does not distinguish between coastal and open ocean. While the area extent of the available air-sea flux estimates varies between products, there are consistent patterns; nearly all products cover the open ocean, whereas larger differences exist in the coverage of coastal regions, shelf seas, marginal seas and the Arctic Ocean. To account for differing area coverage, past studies (Friedlingstein et al., 2019, 2020; Hauck et al., 2020) have adjusted simply by scaling based on the percent of the total ocean area covered by each observation-based product. This does not account for the fact that some areas have CO_2 flux densities that are higher or lower than the global average. Thus, the magnitude of the adjustment by area-scaling is likely an underestimate (McKinley et al., 2020). One specific example is the northern high latitudes where coverage by the six products varies substantially. Similarly, three products provide estimates in marginal seas such as the Mediterranean while the other three products have no reported pCO_2 values here. Shutler et al., (2016) report that subtle differences in regional definitions can cause differences of >10% in the calculated net fluxes.

ACCEPTED VERSION SUBJECT TO FINAL EDITS

To address the inconsistent spatial coverage in products we utilise a newly released open and coastal merged climatology product (MPI-ULB-SOMFFN; Landschützer et al., 2020b) that is a blend of the coastal ocean SOMFFN mapping method (Laruelle et al., 2017) and the open ocean equivalent (MPI-SOMFFN; Landschützer et al., 2020a), but which now includes missing coastal ocean regions, marginal seas and the full Arctic Ocean. For each observationally-based product, we fill missing grid cells with a scaled value based on this global-coverage climatology. The scaling accounts for year-to- year changes in pCO_2 in the missing areas (given that the extended MPI-ULB-SOMFFN product is a monthly climatology centred on year 2006) and is obtained as follows. To extend the open and coastal merged monthly climatology (MPI-ULB-SOMFFN) to 1988–2018, we calculate a global scaling factor based on the product-based ensemble mean pCO_2 for regions which are covered consistently by all six pCO_2 products. We first mask all pCO_2 products to a common sea mask before taking an ensemble mean (pCO_2^{ens}). Next, we divide this ensemble mean by the MPI-ULB-SOMFFN climatology (pCO_2^{clim}) at monthly 1° by 1° resolution (Equation 2). The monthly scaling factor ($sf\,pCO_2$) is calculated by taking the mean over the spatial dimensions.

The scaling factor calculation can be represented as:

$$sf_{pCO_2} = mean_{x,y}\left(\frac{pCO_2^{ens}}{pCO_2^{clim}}\right) \qquad (2)$$

where $sfpCO_2$ is the one-dimensional scaling factor (time dimension), pCO_2^{ens} is the ensemble mean of all pCO_2 products at three-dimension, monthly 1° by 1° resolution, pCO_2^{clim} is the MPI-ULB-SOMFFN climatology, also at three-dimension but limited to just one climatological year. The *x* and *y* indicate that we take the area-weighted average over longitude (*x*) and latitude (*y*) resulting in the monthly scaling value. If a product mean is exactly equal to the climatology mean, the scaling factor is 1. Value ranges from 0.91 to 1.06 over the 31-year time period. The one-dimensional scaling factor is then multiplied by the MPI-ULB-SOMFFN climatology for each spatial point resulting in a three-dimensional scaled filling map. These values are then used to fill in missing grid cells in each observation-based product. Globally, the adjustments are all less than 20% of the total flux, with the mean adjustment for the six products at 9%. In the Northern Hemisphere however, the filling process can drive adjustments of up to 35%. As expected, the observationally-based products with more complete spatial coverage tend to have smaller flux adjustments, however the impact on the final CO_2 flux depends on the ΔpCO_2 and wind speed of the areas being filled. The only product that does not change during this adjustment process is the JENA-MLS mixed layer scheme-based product (Rödenbeck et al., 2013) which is produced with full spatial coverage and therefore needs no spatial filling.

Our approach is not without its own assumptions and limitations. We rely on a single estimate of the missing pCO_2 in coastal ocean regions, marginal seas, and the full Arctic Ocean, given that this is the only publicly available product currently existing. Nevertheless, the fact that common missing areas along coastal regions and marginal seas are reconstructed using specific coastal observations provides a step forward from the linear-scaling approach currently used by the Global Carbon Budget (Friedlingstein et al., 2019, 2020). Further confidence is provided by previous research showing that climatological relevant signals, i.e. mean state and seasonality, are well reconstructed by the MPI-SOMFFN method.

Furthermore, our scaled filling methodology assumes that pCO_2 in the missing ocean regions is increasing at the same rate as the common area of open-ocean pCO_2 used to calculate the scaling factor. Research from coastal ocean regions and shelf seas reveal that, in spite of a large spatial heterogeneity, this is a reasonable first order approximation (Laruelle et al., 2017). While our approach has a constant scaling factor for the missing ocean areas regardless of latitude we acknowledge that this could be improved with increased understanding.

Step 2: Wind product selection

180 Historical wind speed observations (including measurements from satellites and moored buoys) are aggregated and extrapolated through modelling and data assimilation systems to create global wind reanalyses. These reanalyses are required to compute air-sea gas exchange. Air-sea flux is commonly parameterised as a function of the gradient of CO_2 between the ocean and the atmosphere with wind speed

ACCEPTED VERSION SUBJECT TO FINAL EDITS

modulating the rate of the gas exchange (Equation 1). Each of these wind reanalyses has strengths and weaknesses, specifically on regional and seasonal scales (Chaudhuri et al., 2014; Ramon et al., 2019) but all are considered reasonable options by the community (Roobaert et al., 2018). We use three wind reanalysis products for completeness: the Cross-Calibrated Multi-Platform v2 (CCMP2, (Atlas et al., 2011)), the Japanese 55-year Reanalysis (JRA-55, KOBAYASHI et al., 2015) and the European Centre for Medium-Range Weather Forecasts (ECMWF) ERA5 (Hersbach et al., 2020). The wind speed (U10) is calculated at the native resolution of each wind product from the u- and v-components of wind.

Step 3: Calculation of gas exchange coefficient

We employ the quadratic windspeed dependence of the gas transfer velocity (Wanninkhof, 1992) and calculate the piston velocity (*kw*) for each of the wind reanalysis products as:

$$k_W = a \cdot \langle U^2 \rangle \cdot \left(Sc/_{660}\right)^{-0.5} \quad (3)$$

where the units of k_W are in cm h^{-1}, *Sc* is the dimensionless Schmidt number, and $\langle U^2 \rangle$ denotes the second moment of average 10-m height winds (m s^{-1}). We choose the quadratic dependence of the gas transfer velocity as it is widely accepted and used in the literature (Wanninkhof, 1992). Observational and modelling studies have often suggested that different parametrizations could be more appropriate under specific conditions (Fairaill et al., 2000; Nightingale et al., 2000; McGillis et al., 2001; Krakauer et al., 2006); however, recent direct carbon dioxide flux measurements made in the high latitude Southern Ocean confirm that even in this high wind environment, a quadratic parameterization fits the observations best (Butterworth and Miller, 2016). Future updates of the SeaFlux product will include options for other parameterizations. We calculate the square of the wind speed at the native resolution of each wind product and then average it to 1° by 1° monthly resolution. The order of this calculation is important as information is lost when resampling data to lower resolutions because of the concavity of the quadratic function. For example, if the second moment were calculated from time-averaged wind speeds, it would result in an underestimate of the gas transfer velocity (Sarmiento and Gruber 2006; (Sweeney et al., 2007). The resulting second moment is equivalent to $\langle U^2 \rangle = U_{mean}^2 + U_{std}^2$ where U_{mean} and U_{std} are the temporal mean and standard deviation calculated from the native temporal resolution of U.

In addition to the choice of wind parameterization, large differences in flux can result due to the scaling coefficient of gas transfer (*a*) that is applied when calculating the global mean piston velocity. This constant originates from the gas exchange process studies (Krakauer et al., 2006; Sweeney et al., 2007; Müller et al., 2008; Naegler, 2009) utilise observations of radiocarbon data from the GEOSECS and WOCE/JGOFS expeditions (Key et al., 2004). The ^{14}C released from nuclear bomb testing (hence bomb-^{14}C) in the mid twentieth century has since been taken up by the ocean. The number of bomb-^{14}C atoms in the ocean, relative to the pre-bomb ^{14}C, can thus be used as a constraint on the long-term rate of exchange of carbon between the atmosphere and the ocean. A probability distribution of wind speed is used to optimise the coefficient of gas transfer based on these observed natural and bomb ^{14}C invasion rates. This coefficient must be individually calculated and is not consistent for each wind product. Further, the gas transfer velocity used by the different pCO_2 mapping products are not scaled to the same bomb-^{14}C estimate. The range of the different bomb-^{14}C estimates is within the range of the uncertainty from the associated studies (Naegler, 2009), but the choice would introduce inconsistency that is easily addressed here.

We scale the gas transfer velocity to a bomb-^{14}C flux estimate of 16.5 cm hr^{-1} as recommended by Naegler, (2009). The coefficient (*a*) is calculated for each wind product via a cost function which optimises the coefficient of gas transfer

$$a = k_W \cdot \langle U^2 \rangle^{-1} \cdot \left(Sc/_{660}\right)^{0.5} \cdot (1 - ice) \quad (4)$$

where parameters are as defined in Equation 3. The units of the coefficient a are (cm h^{-1}) (m s^{-1})$^{-2}$. Global winds from the wind speed products differ and therefore even with the same bomb-^{14}C observations the scaled coefficient (a) can have a 40% range (Wanninkhof, 2014). By determining the optimal a coefficient

ACCEPTED VERSION SUBJECT TO FINAL EDITS

for each of the reanalysis winds, uncertainty in the global fluxes can be decreased. Our scaled coefficients correspond well with the estimate of Wanninkhof, (2014) who uses the CCMP wind product to estimate a as 0.251. Differences in the coefficient will also result from the time period considered and definition of global area and ice fraction applied in the calculation.

This scaling of the gas exchange coefficient (a) for each wind product is an essential, and an inconsistently applied step, that has large implications for air-sea flux estimates. Without individual scaling, and instead utilising a set value for the gas transfer coefficient (a) regardless of wind product, our results show that calculated global fluxes could be as high as 9% different depending on which pCO_2 and wind reanalysis product considered (Roobaert et al., 2018).

Step 4: Further parameters for flux calculation

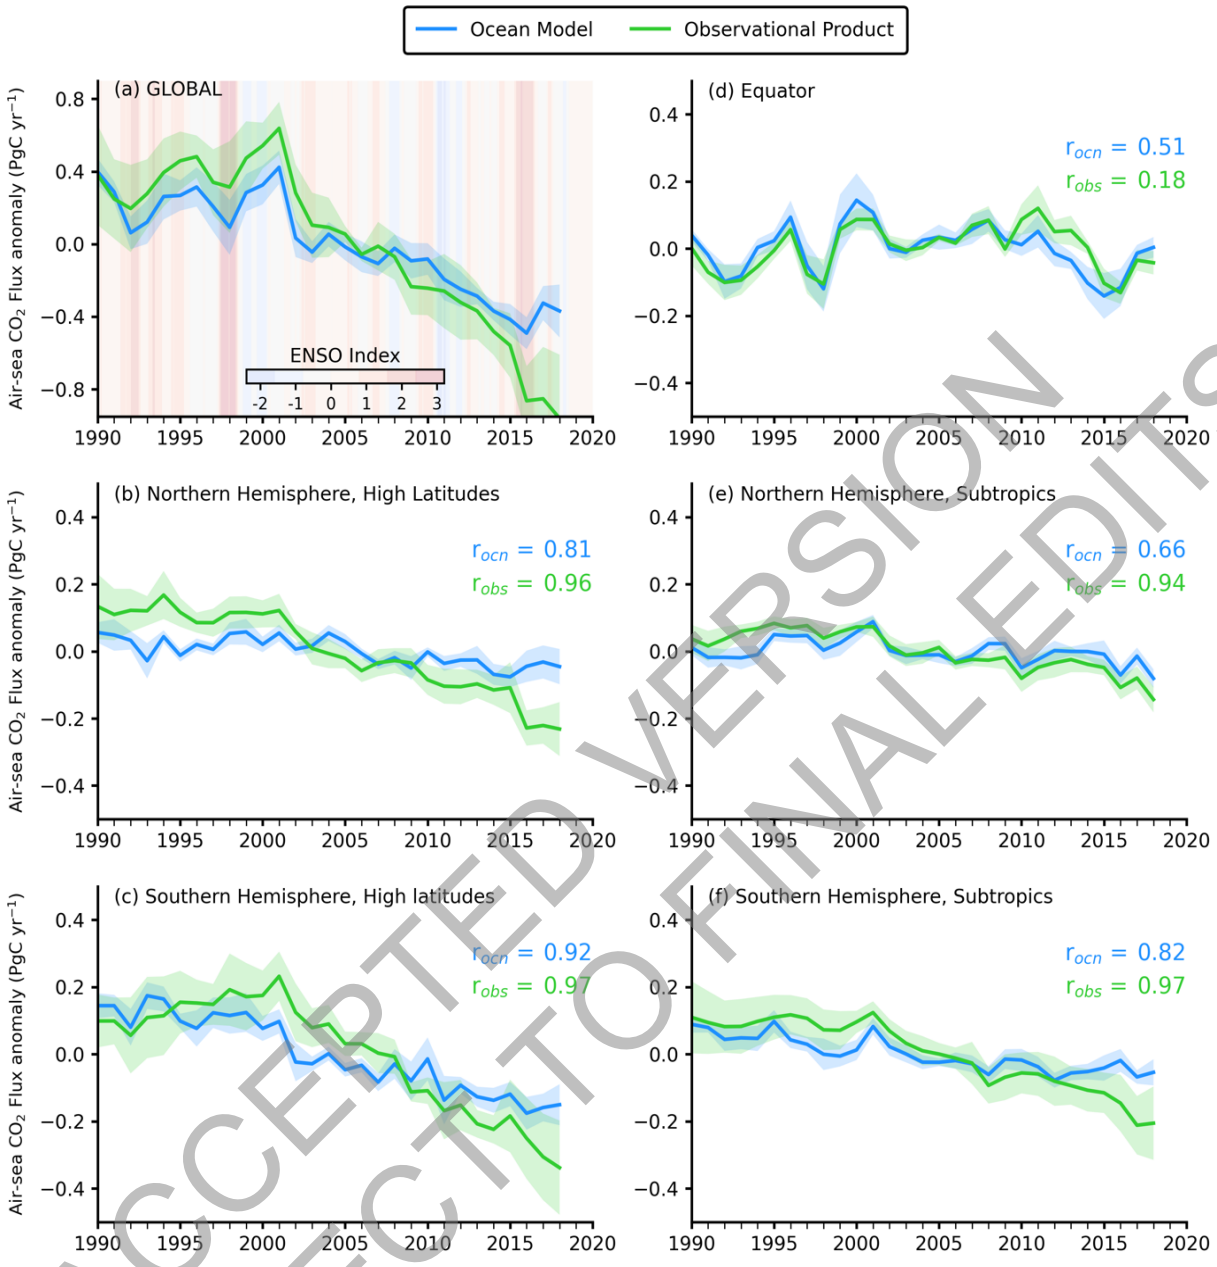
The remaining parameters of Equation 1 are the solubility of CO_2 in seawater (*sol*), the atmospheric partial pressure of CO_2 (pCO_2^{atm}), and the area weighting to account for sea ice cover. While the choices of products used for these parameters can also result in differences in flux estimates, the impacts are much smaller as compared with the parameters discussed above.

Atmospheric pCO_2 is calculated as the product of surface xCO_2 and sea level pressure corrected for the contribution of water vapor pressure. The choice of the sea level pressure product, or absence of the water vapor correction can have small, but not insignificant, impact on the calculated fluxes. Additionally, some products utilise the output of an atmospheric CO_2 inversion product (e.g. CarboScope, (Rödenbeck et al., 2013), CAMS CO_2 inversion) (Chevallier, 2013) which can introduce differences in the flux estimate outside of the sources related to a product's surface ocean pCO_2 mapping method. Importantly, we do not advocate that our estimate of pCO_2^{atm} is an improvement over other estimates thereof, rather we provide an estimate of pCO_2^{atm} that has few assumptions and leads to a methodologically consistent estimate of ΔpCO_2. We maintain the same philosophy in our estimates of solubility of CO_2 in seawater and sea-ice area weighting and therefore we do not elaborate on them here.

5.SM.3 Biogeophysical sequestration potential of ocean-based CDR methods

Ocean fertilisation (OF) aims to boost primary production and subsequently organic carbon export by seeding the ocean surface with nutrients, typically in iron-limited areas such as the Southern Ocean or North Pacific. Iron fertilisation experiments have been inconclusive on whether deep-sea carbon sequestration is enhanced (Boyd et al., 2007; Yoon et al., 2018), with only one observing an increase in the biological pump below 1000 m (Smetacek et al., 2012), suggesting that the effectiveness of ocean fertilisation is low (*medium confidence*). Model simulations (Oschlies et al., 2010; Keller et al., 2014) suggest that if ocean fertilisation is applied continuously in the Southern Ocean under high CO_2 emission scenarios, CO_2 sequestration rates are initially between 2 and 4 PgC yr^{-1}, but then decrease to 0.4 to 1 PgC yr^{-1} after the initial decade, with an 80-year cumulative carbon uptake of 73 to 90 PgC. Taking the sequestration rates from these model simulations to constitute an upper limit, we assess the maximum biogeophysical sequestration potential of iron fertilization to be 1 PgC yr^{-1} (*low confidence*). Increased productivity in the fertilised areas would result in decreased productivity in unfertilised regions (Oschlies et al., 2010b). The carbonate counter pump could also reduce iron fertilisation-induced carbon sequestration by 6–32% (Salter et al., 2014).

Artificial ocean upwelling (AOUpw) brings nutrient-rich water to the ocean surface to alleviate nutrient limitation of (near-) surface phytoplankton growth and thus boost primary production and subsequent ocean CO_2 uptake. For AOUpw to be effective at increasing ocean carbon storage, the increased primary production has to result in increased transfer of organic carbon into the deep ocean. AOUpw also returns previously-sequestered dissolved inorganic carbon to the surface ocean, thus increasing surface water pCO_2 and decreasing (or potentially negating) atmospheric CO_2 drawdown stimulated by the additional nutrient input. In model simulations (Oschlies, 2010; Keller et al., 2014) where AOUpw is applied continuously and at the largest feasible scales, atmospheric CO_2 removal is up to 4.3 PgC yr^{-1} during the first decade, and decreases afterwards to 0.9 to 1.5 PgC yr^{-1} (average), with an 80-year cumulative CO_2 removal of 80 to 140



ACCEPTED VERSION SUBJECT TO FINAL EDITS

PgC. 50–80% of this removal results from cooling-induced enhancement of the terrestrial carbon sink (Keller et al., 2014). Removing terrestrial CO_2 removal from the total cumulative CO_2 removal yields cumulative ocean CO_2 removal of 16 to 70 PgC over 80 years, or 0.2 to 0.9 PgC yr^{-1} (*low confidence*).

Ocean alkalinisation, via the deposition of alkaline minerals (e.g. olivine) or their dissociation products (e.g. quicklime) at the ocean surface, can increase surface total alkalinity and thus increase CO_2 uptake and storage. Modelling studies suggest that massive additions of alkalinity (114 Pmol by the end of the century) in high CO_2 emission scenarios could increase ocean uptake by up to 27 PgC yr^{-1} by the end of the century (cumulative atmospheric CDR of up to 905 PgC), and permanently keep it there (100 ka residence time; Renforth & Henderson, 2017) even if additions were stopped (González et al., 2016; Feng et al., 2017; Sonntag et al., 2018). Taking the sequestration rates from these model simulations to constitute an upper limit, we assess the maximum biogeophysical sequestration potential of ocean alkalinisation to be 10 PgC yr^{-1} *(medium confidence*).

[START TABLE 5.SM.4 HERE]

Table 5.SM.4: Explanation and references of earth system feedbacks, biogeochemical and biophysical impacts, and trade-offs and co-benefits of the carbon dioxide removal (CDR) methods as presented in Figure 5.37.

CDR Method	Earth system feedbacks on CO_2 sequestration potential and temperature	Biogeochemical and biophysical effects	Trade-offs and co-benefits related to water quantity and quality, food supply, biodiversity (BD)
Afforestation, reforestation and forest management	Weakens ocean C sequestration through decreased [CO_2] (Keller et al., 2018; Sonntag et al., 2018); decrease in albedo due to afforestation weakens the effect of CO_2 removal on surface air temperature (Sonntag et al., 2018); may shift the location of the Intertropical Convergence Zone and hence precipitation in the monsoon regions (Devaraju et al., 2015a)	Increased emissions of biogenic volatile organic compounds (BVOC) (Krause et al., 2017, SRCCL Sections 2.5.2.1, 2.6.1.2), decreased and increased surface temperature, in tropics and boreal region, respectively, due to changes in albedo, evapotranspiration and surface roughness (SRCCL Section 2.5.2.1; Fuss et al., 2018; Griscom et al., 2017; Pongratz et al., 2010; Jackson et al., 2008; Bright et al., 2015; Devaraju et al., 2015); decreased (Chen et al., 2019; Zhou et al., 2019; Deng et al., 2019) or increased (Benanti et al., 2014) N_2O emissions; increased CH_4 uptake (Chen et al., 2019; Nisbet et al., 2020)	Threatened water supply in dry areas regional climate, initial land cover, and scale of deployment (Farley et al., 2005; Mengis et al., 2019); improved water quality due to higher soil water retention and filtering capacity (Smith et al., 2019); affects food supply through competition for land (Smith et al., 2018b); decreased BD if not adopted wisely, increased BD if monocultures are replaced by native species (Smith et al., 2018; Williamson & Bodle, 2016); potentially negative impacts on food security due to land requirements (Smith et al., 2020).
Soil carbon sequestration	Weakens ocean C sequestration through decreased [CO_2] (Keller et al., 2018)	Decreased or increased N_2O emissions, depending on management strategy, fertilization, land-use, use of cover crops (Smith et al., 2016; Gu et al., 2017; Fuss et al., 2018b) Small or negligible impact on soil CH_4 flux (Smith et al., 2008); Albedo increase by no-till farming (Davin et al., 2014)	Reduced nutrient losses, increased biological activity (Fornara et al., 2011; Paustian et al., 2016; Tonitto et al., 2006; (Fuss et al., 2018b; Smith, 2016), improved soil water holding capacity (Paustian et al., 2019), positive impact on food security due to increased yield (Smith et al., 2020); no impact or increased BD, depending on method (Paustian et al., 2016; Smith et al., 2018b)
Biochar	Weakens ocean C sequestration through decreased [CO_2] (Keller et al., 2018)	Decreased N_2O emissions (Cayuela et al., 2014; Kammann, 2017), decreased CH_4 uptake in non-inundated soils (Jeffery et al., 2016); decreased CH_4 emissions in inundated soils such as rice fields (Jeffery et al., 2016; Yang et al., 2019; Wang et al., 2019; Huang et al., 2019), local warming related to darkened surface (Genesio et al., 2012; Zhang et al., 2018; Jia et al., 2019, SRCCL); VOC's	Improved soil fertility and productivity, reduced nutrient losses, enhanced fertiliser N use efficiency (Clough et al., 2013; Liu et al., 2017; Shen et al., 2016, Woolf et al., 2010); improved soil water holding capacity (Karhu et al., 2011; Verheijen et al., 2019; C. Liu et al., 2016; Bock et al., 2017; Fischer et al., 2019); no impact or increased BD (Smith et al., 2018); adverse impacts on BD due to land

ACCEPTED VERSION SUBJECT TO FINAL EDITS

		produced when preparing biochar can be toxic to plants and animals (Buss and Mašek, 2016)	requirements of feedstock (12.3.3, WGIII); benefits for food security due to improved yields (Smith et al., 2020)
Peatland restoration	no evidence	Enhanced CH_4 emission (Vanselow-Algan et al., 2015; Wilson et al., 2016; Renou-Wilson et al., 2019; Hemes et al., 2019; Holl et al., 2020); suppressed N_2O emissions (Wilson et al., 2016; Liu et al., 2020; Tiemeyer et al., 2020); increased (Koskinen et al., 2017) or decreased (Singh et al., 2019) leaching of nutrients; surface cooling due to higher evapotranspiration (Hemes et al., 2018; Helbig et al., 2020; Worrall et al., 2019)	Increased nutrient infiltration and retention to increase water quality (Daneshvar et al., 2017; Kluber et al., 2014; Lundin et al., 2017); protection from fire, increased BD (Meli et al., 2014; Smith et al., 2018b)
Restoration of vegetated coastal ecosystems (‘blue carbon’)	no evidence	Emission of CH_4 and N_2O, and biogenic calcification may partly offset benefits (Rosentreter et al., 2018; Keller, 2019; Kennedy et al., 2019)	Provision of very wide range of ecosystem services (biodiversity support recreation and tourism; fishery habitats; improved water quality, and flood and erosion protection) (Bindoff et al., 2019)
Ocean fertilisation	Carbonate counter pump could decrease C sequestration (Salter et al., 2014); Weakens terrestrial C storage (Keller et al., 2018)	Enhanced subsurface ocean acidification (Cao and Caldeira, 2010; Williamson et al., 2012a; Oschlies, 2009); Increased suboxic zone extent in fertilised areas; Shrinkage of suboxic zones outside fertilised areas (Oschlies, 2009; Keller et al., 2014); Increased production of N_2O and CH_4 (Jin and Gruber, 2003; Lampitt et al., 2008)	Perturbation to marine ecosystems via reorganisation of community structure, including possibly toxic algal blooms (Oschlies et al., 2010a; Williamson et al., 2012)
Artificial ocean upwelling	Cooling effect; increases terrestrial C storage (Oschlies et al., 2010b; Keller et al., 2014; Kwiatkowski et al., 2015); Returns previously sequestered C to ocean surface, decreasing or potentially negating CO_2 drawdown (Bauman et al., 2014; Kwiatkowski et al., 2015)	Enhanced subsurface ocean acidification (Cao and Caldeira, 2010; Oschlies et al., 2010c; Williamson et al., 2012a); Increased suboxic zone extent in fertilised areas (Keller et al., 2014; Feng et al., 2020); alters ocean temperature, salinity, circulation (Keller et al., 2014b); alters Earth’s heat and water budget (Keller et al., 2014); increased production of N_2O and CH_4 (Jin and Gruber, 2003; Lampitt et al., 2008; Williamson et al., 2012a)	Perturbation to marine ecosystems via reorganisation of community structure, including possibly toxic algal blooms (Oschlies et al., 2010a; Williamson et al., 2012)
Ocean alkalinisation	Increased ocean C storage through enhanced primary production through addition of iron and silicic acid from olivine dissolution (Köhler	Decreased ocean acidification (surface waters only); decreased de-oxygenation (González and Ilyina, 2016)	Release of toxic trace metals from some deposited minerals (Hartmann et al., 2013) Perturbation to marine ecosystems via

ACCEPTED VERSION SUBJECT TO FINAL EDITS

	et al., 2013; Hauck et al., 2016); Lowers terrestrial carbon storage (González and Ilyina, 2016; Sonntag et al., 2018)		reorganisation of community structure (González and Ilyina, 2016; González et al., 2018)
Enhanced weathering - terrestrial	Will initially reduce the ocean CO_2 sequestration, but after enough weathering products are transported into ocean to increase alkalinity, will increase ocean CO_2 sequestration (Keller et al., 2018)	Decreased N_2O emissions (Blanc-Betes et al; Kantola et al., 2017); reduced ocean acidification (Beerling et al., 2018)	Soil fertilisation and stimulated biological production (Hartmann et al., 2013); can liberate toxic trace metals into soil or water bodies (Keller et al., 2018); can decrease drinking water quality by causing freshwater salinization (Kaushal et al., 2018); increases alkalinity and pH of natural waters (Beerling et al., 2018); adverse impact on BD from mining (Smith et al., 2018)
BECCS	Weakens ocean C sequestration through decreased [CO_2] (Keller et al. 2018); Can weaken or strengthen land C sequestration depending on whether bioenergy crops replace marginal land or carbon-rich ecosystems (Don et al., 2012; Heck et al., 2016; Boysen et al., 2017a,b) (Harper et al., 2018)	Increased N_2O emissions related to land-use or if fertilized (Creutzig et al., 2015; Smith et al., 2016); local warming due to decreased albedo depending on the type of bioenergy crop (Smith et al., 2016); VOC emissions (Krause et al., 2017)	Threatened water supply (Farley et al., 2005; Smith et al., 2016, Cross-chapter box 5.1); threatened food supply through competition for land (Smith et al., 2019); soil nutrient deficiency; decreased BD depending on scale and previous land-use (Smith et al., 2018; Creutzig et al., 2019; Heck et al., 2018); see DACCS for storage-related side effects
Direct air carbon capture and storage (DACCS)	Weakens ocean and land C sequestration through decreased [CO_2] (Tokarska and Zickfeld, 2015; Jones et al., 2016; Zickfeld et al., 2021)	No evidence or not applicable	Perturbation of marine ecosystems through leakage of CO_2 from submarine storage (Molari et al., 2018); potentially decreased BD due to land and water requirements (Williamson, P., & Bodle, 2016); water use or production (Fuss et al., 2018; NASEM, 2019); VOC emissions in solid-sorbent systems (NASEM, 2019); Storage related: pollution of drinking water; seismic activity, leaks (Fuss et al., 2018)

[START TABLE 5.SM.5 HERE]

Table 5.SM.5: Carbon dioxide removal (CDR) Potentials: Details underlying sequestration potentials classification shown in Figure 5.37.

CDR Method	Technical/ biogeophysical sequestration potential class*	Confidence level	Technical/ biogeophysical sequestration potential median and range**	Sequestration potential category	Data source
Afforestation, reforestation and forest management	Large	Medium (large evidence, medium agreement)	Afforestation, reforestation: 3.7 (0.5–10) $GtCO_2e\ yr^{-1}$; forest management 1.8 (1–2.1) $GtCO_2e\ yr^{-1}$	Technical potential; estimates also consider environmental and social factors	Median and range calculated based on technical and sustainable potentials from (Roe et al., 2019a)
Soil carbon sequestration	Moderate	Medium (large evidence, medium agreement)	Croplands: 1.6 (0.4–6.8) $GtCO_2e\ yr^{-1}$; Pasture lands: 0.7 (0.15–2.6) $GtCO_2e\ yr^{-1}$	Technical potential; estimates also consider environmental and social factors	Median and range calculated based on technical and sustainable potentials from (Roe et al., 2019b)
Biochar	Moderate	Medium (medium evidence, medium agreement)	1.1 (0.1–4.9) $GtCO_2e\ yr^{-1}$	Technical potential; estimates also consider environmental and social factors	Median and range calculated based on technical and sustainable potentials from (Roe et al., 2019b)
Peatland restoration	Moderate	Low (low evidence)	0.7 (0.6–0.8) $GtCO_2e\ yr^{-1}$	Technical potential; estimates also consider environmental and social factors	Median and range calculated based on technical and sustainable potentials from (Roe et al., 2019b)
Restoration of vegetated coastal ecosystems (‘blue carbon’)	Low	Low (low evidence)	0.2–0.7 $GtCO_2\ yr^{-1}$ (0.05–0.2 $GtC\ yr^{-1}$); 0.2–0.8 $GtCO_2\ yr^{-1}$	Technical potential; estimates also consider environmental and social factors	SROCC Ch 5 (IPCC, 2019); Range calculated based on technical and sustainable potentials from (Roe et al., 2019b)
Ocean iron fertilization	Large	Low (medium evidence, low agreement)	<3.7 $GtCO_2\ yr^{-1}$ (<1 $GtC\ yr^{-1}$); 3.7 $GtCO_2\ yr^{-1}$ (1 $GtC\ yr^{-1}$); 3.7 (0–44) $GtCO_2\ yr^{-1}$	Biogeophysical potential	Supplementary Material 5.SM3; (GESAMP, 2019) Table 4.4; median and range based on global studies considered in (Fuss et al., 2018)

ACCEPTED VERSION SUBJECT TO FINAL EDITS

Artificial ocean upwelling	Moderate	Low (low evidence)	0.7–3.3 $GtCO_2\ yr^{-1}$ (0.2–0.9 GtC yr^{-1}); <0.7 $GtCO_2\ yr^{-1}$ (< 0.2 GtC/yr)	Biogeophysical potential	Supplementary Material 5.SM3; (GESAMP, 2019) Table 4.4
Ocean alkalinization	Large	Medium (medium evidence, medium agreement)	<37 $GtCO_2\ yr^{-1}$ (<10 GtC yr^{-1}); 3.7 $GtCO_2\ yr^{-1}$ (1 GtC yr^{-1}); 1–99 $GtCO_2\ yr^{-1}$	Biogeophysical potential	Supplementary Material 5.SM3; (GESAMP, 2019) Table 4.4; full range (Fuss et al., 2018)
Enhanced weathering	Large	Medium (medium evidence, low agreement)	3.7 (1–95) $GtCO_2\ yr^{-1}$	Technical potential	Median and range based on global studies considered in (Fuss et al., 2018)
BECCS	Large	Medium (medium evidence, medium agreement)	4.6 (0.4–11.3) $GtCO_2\ yr^{-1}$	Technical potential; estimates also consider environmental and social factors	Median and range calculated based on technical and sustainable potentials from (Roe et al., 2019b)
DACCS	Large	Medium (low evidence, large agreement)	5–40 $GtCO_2\ yr^{-1}$	Technical potential	Full range (Fuss et al., 2018)

*Potentials classes: Low <0.3 $GtCO_2\ yr^{-1}$; Moderate 0.3–3 $GtCO_2\ yr^{-1}$; Large >3 $GtCO_2\ yr^{-1}$; classification based on *median* potentials estimate

**WGIII will present an update of these estimates based on more recent literature

Executive Summary

Short-lived climate forcers (SLCFs) affect climate and are, in most cases, also air pollutants. They include aerosols (sulphate, nitrate, ammonium, carbonaceous aerosols, mineral dust and sea spray), which are also called particulate matter (PM), and chemically reactive gases (methane, ozone, some halogenated compounds, nitrogen oxides, carbon monoxide, non-methane volatile organic compounds, sulphur dioxide and ammonia). Except for methane and some halogenated compounds whose lifetimes are about a decade or more, SLCFs abundances are highly spatially heterogeneous since they only persist in the atmosphere from a few hours to a couple of months. SLCFs are either radiatively active or influence the abundances of radiatively active compounds through chemistry (chemical adjustments), and their climate effect occurs predominantly in the first two decades after their emission or formation. They can have either a cooling or warming effect on climate, and they also affect precipitation and other climate variables. Methane and some halogenated compounds are included in climate treaties, unlike the other SLCFs that are nevertheless indirectly affected by climate change mitigation since many of them are often co-emitted with CO_2 in combustion processes. This chapter assesses the changes, in the past and in a selection of possible futures of the emissions and abundances of individual SLCFs primarily on a global and continental scale, and how these changes affect the Earth's energy balance through radiative forcing and feedback in the climate system. The attribution of climate and air-quality changes to emission sectors and regions, and the effects of SLCF mitigations defined for various environmental purposes, are also assessed.

Recent Evolution in SLCF Emissions and Abundances

Over the last decade (2010–2019), strong shifts in the geographical distribution of emissions have led to changes in atmospheric abundances of highly variable SLCFs (*high confidence*). Evidence from satellite and surface observations show strong regional variations in trends of ozone (O_3), aerosols and their precursors (*high confidence*). In particular, tropospheric columns of nitrogen dioxide (NO_2) and sulphur dioxide (SO_2) continued to decline over North America and Europe (*high confidence*) and to increase over South Asia (*medium confidence*), but have declined over East Asia (*high confidence*). Global carbon monoxide (CO) abundance has continued to decline (*high confidence*). The concentrations of hydrofluorocarbons (HFCs) are increasing (*high confidence*). Global carbonaceous aerosol budgets and trends remain poorly characterized due to limited observations, but sites representative of background conditions have reported multi-year declines in black carbon (BC) over several regions of the Northern Hemisphere. {6.2, 6.3, 2.2.4, 2.2.5, 2.2.6}

There is no significant trend in the global mean tropospheric concentration of hydroxyl (OH) radical – the main sink for many SLCFs, including methane (CH_4) – from 1850 up to around 1980 (*low confidence*) but OH has remained stable or exhibited a positive trend since the 1980s (*medium confidence)*. Global OH cannot be measured directly and is inferred from Earth system and climate chemistry models (ESMs, CCMs) constrained by emissions and from observationally constrained inversion methods. There is conflicting information from these methods for the 1980–2014 period. ESMs and CCMs concur on a positive trend since 1980 (about a 9% increase over 1980–2014) and there is *medium confidence* that this trend is mainly driven by increases in global anthropogenic nitrogen oxide (NO_x) emissions and decreases in anthropogenic CO emissions. The observation-constrained methods suggest either positive trends or the absence of trends based on *limited evidence and medium agreement.* Future changes in global OH, in response to SLCF emissions and climate change, will depend on the interplay between multiple offsetting drivers of OH. {6.3.6 and Cross-Chapter Box 5.1}

Effect of SLCFs on Climate and Biogeochemical Cycles

Over the historical period, changes in aerosols and their ERF have primarily contributed to a surface cooling, partly masking the greenhouse gas driven warming (*high confidence*). Radiative forcings induced by aerosol changes lead to both local and remote temperature responses (*high confidence*). The temperature response preserves the South-North gradient of the aerosol ERF – hemispherical asymmetry- but is more uniform with latitude and is strongly amplified towards the Arctic (*medium confidence*). {6.4.1, 6.4.3}

Since the mid-1970s, trends in aerosols and their precursor emissions have led to a shift from an

ACCEPTED VERSION SUBJECT TO FINAL EDITING

increase to a decrease of the magnitude of the negative globally-averaged net aerosol ERF (*high confidence*). However, the timing of this shift varies by continental-scale region and has not occured for some finer regional scales. The spatial and temporal distribution of the net aerosol ERF from 1850 to 2014 is highly heterogeneous, with stronger magnitudes in the Northern Hemisphere (*high confidence*). {6.4.1}

For forcers with short lifetimes (e.g., months) and not considering chemical adjustments, the response in surface temperature occurs strongly as soon as a sustained change in emissions is implemented, and that response continues to grow for a few years, primarily due to thermal inertia in the climate system (*high confidence*). Near its maximum, the response slows down but will then take centuries to reach equilibrium (*high confidence*). For SLCFs with longer lifetimes (e.g., a decade), a delay equivalent to their lifetimes is appended to the delay due to thermal inertia (*high confidence*). {6.6.1}

Over the 1750-2019 period, changes in SLCF emissions, especially of CH_4, NO_x and SO_2, have substantial effects on effective radiative forcing (ERF) (*high confidence*). The net global emissions-based ERF of NO_x is negative and that of non-methane volatile organic compounds (NMVOCs) is positive, in agreement with the AR5 assessment (*high confidence*). For methane, the emission-based ERF is twice as high as the abundance-based ERF (*high confidence*) attributed to chemical adjustment mainly via ozone production. SO_2 emission changes make the dominant contribution to the ERF from aerosol–cloud interactions (*high confidence*). Over the 1750-2019 period, the contributions from the emitted compounds to GSAT changes broadly match their contributions to the ERF (*high confidence*). Since a peak in emissions-induced SO_2 ERF has already occurred recently and since there is a delay in the full GSAT response, changes in SO_2 emissions have a slightly larger contribution to GSAT change than for CO_2 emissions, relative to their respective contributions to ERF. {6.4.2, 6.6.1 and 7.3.5}

Reactive nitrogen, ozone and aerosols affect terrestrial vegetation and the carbon cycle through deposition and effects on large scale radiation (*high confidence*). However, the magnitude of these effects on the land carbon sink, ecosystem productivity and hence their indirect CO_2 forcing remain uncertain due to the difficulty in disentangling the complex interactions between the individual effects. As such, these effects are assessed to be of second order in comparison to the direct CO_2 forcing (*high confidence*), but effects of ozone on terrestrial vegetation could add a substantial (positive) forcing compared with the direct ozone forcing (*low confidence*). {6.4.5}

Climate feedbacks induced from changes in emissions, abundances or lifetimes of SLCFs mediated by natural processes or atmospheric chemistry are assessed to have an overall cooling effect (*low confidence*), that is, a total negative feedback parameter, of -0.20 [-0.41 to +0.01] W m^{-2} $°C^{-1}$. These non-CO_2 biogeochemical feedbacks are estimated from ESMs, which have advanced since AR5 to include a consistent representation of biogeochemical cycles and atmospheric chemistry. However, process-level understanding of many chemical and biogeochemical feedbacks involving SLCFs, particularly natural emissions, is still emerging, resulting in *low confidence* in the magnitude and sign of most of SLCF climate feedback parameter. {6.2.2, 6.4.5}

Future Projections for Air Quality Considering Shared Socio-economic Pathways (SSPs)

Future air quality (in term of surface ozone and PM concentrations) on global to local scales will be primarily driven by changes in precursor emissions as opposed to climate change (*high confidence*) and climate change is projected to have mixed effects. A warmer climate is expected to reduce surface O_3 in regions remote from pollution sources (*high confidence*) but is expected to increase it by a few parts per billion over polluted regions, depending on ozone precursor levels (*medium to high confidence*). Future climate change is expected to have mixed effects, positive or negative, with an overall low effect, on global surface PM and more generally on the aerosol global burden (*medium confidence*), but stronger effects are not excluded in regions prone to specific meteorological conditions (*low confidence*). Overall, there is *low confidence* in the response of surface ozone and PM to future climate change due to the uncertainty in the response of the natural processes (e.g., stratosphere–troposphere exchange, natural precursor emissions, particularly including biogenic volatile organic compounds, wildfire-emitted precursors, land and marine aerosols, and lightning NO_x) to climate change. {6.3, 6.5}

ACCEPTED VERSION SUBJECT TO FINAL EDITING

The SSPs span a wider range of SLCF emissions than the Representative Concentration Pathways, representing better the diversity of future options in air pollution management (*high confidence*). In the SSPs, the socio-economic assumptions and climate mitigation ambition primarily drive future emissions, but the SLCF emission trajectories are also steered by varying levels of air pollution control originating from the SSP narratives, independently from climate mitigation. Consequently, SSPs consider a large variety of regional ambition and effectiveness in implementing air pollution legislation and result in wider range of future air pollution levels and SLCF-induced climate effects. {6.7.1}

Air pollution projections range from strong reductions in global surface ozone and PM (e.g., SSP1-2.6, with strong mitigation of both air pollution and climate change) to no improvement and even degradation (e.g., SSP3-7.0 without climate change mitigation and with only weak air pollution control) (*high confidence*). Under the SSP3-7.0 scenario, PM levels are projected to increase until 2050 over large parts of Asia, and surface ozone pollution is projected to worsen over all continental areas through 2100 (*high confidence*). Without climate change mitigation but with stringent air pollution control (SSP5-8.5), PM levels decline through 2100, but high methane levels hamper the decline in global surface ozone at least until 2080 (*high confidence*). {6.7.1}

Future Projections of the Effect of SLCFs on GSAT in the Core SSPs

In the next two decades, it is *very likely* that the SLCF emission changes in the WG1 core set of SSPs will cause a warming relative to 2019, whatever the SSPs, in addition to the warming from long-lived greenhouse gases. The net effect of SLCF and HFC changes on GSAT across the SSPs is a *likely* warming of 0.06°C–0.35°C in 2040 relative to 2019. Warming over the next two decades is quite similar across the SSPs due to competing effects of warming (methane, ozone) and cooling (aerosols) SLCFs. For the scenarios with the most stringent climate and air pollution mitigations (SSP1-1.9 and SSP1-2.6), the *likely* near-term warming from the SLCFs is predominantly due to sulphate aerosol reduction, but this effect levels off after 2040. In the absence of climate change policies and with weak air pollution control (SSP3-7.0), the *likely* near-term warming due to changes in SLCFs is predominantly due to increases in methane, ozone and HFCs, with smaller contributions from changes in aerosols. SSP5-8.5 has the highest SLCF-induced warming rates due to warming from methane and ozone increases and reduced aerosols due to stronger air pollution control compared to the SSP3-7.0 scenario. {6.7.3}

At the end of the century, the large diversity of GSAT response to SLCFs among the scenarios robustly covers the possible futures, as the scenarios are internally consistent and span a range from very high to very low emissions. In the scenarios without climate change mitigation (SSP3-7.0, SSP5-8.5,) the *likely* range of the estimated warming due to SLCFs in 2100 relative to 2019 is 0.4°C–0.9°C {6.7.3, 6.7.4}. In SSP3-7.0 there is a near-linear warming due to SLCFs of 0.08°C per decade, while for SSP5-8.5 there is a more rapid warming in the first half of the century. For the scenarios considering the most stringent climate and air pollution mitigations (SSP1-1.9 and SSP1-2.6), the reduced warming from reductions in methane, ozone and HFCs partly balances the warming from reduced aerosols, and the overall SLCF effect is a *likely* increase in GSAT of 0.0°C–0.3°C in 2100, relative to 2019. The SSP2-4.5 scenario (with moderate climate and air pollution mitigations) results in a *likely* warming in 2100 due to the SLCFs of 0.2°C–0.5°C, with the largest warming from reductions in aerosols. {6.7.3}

Potential Effects of SLCF Mitigation

Over time scales of 10 to 20 years, the global temperature response to a year's worth of current emissions of SLCFs is at least as large as that due to a year's worth of CO_2 emissions (*high confidence*). Sectors producing the largest SLCF-induced warming are those dominated by CH_4 emissions: fossil fuel production and distribution, agriculture and waste management (*high confidence*). On these time scales, SLCFs with cooling effects can significantly mask the CO_2 warming in the case of fossil fuel combustion for energy and land transportation, or completely offset the CO_2 warming and lead to an overall net cooling in the case of industry and maritime shipping (prior to the implementation of the revised fuel-sulphur limit policy for shipping in 2020) (*medium confidence*). Ten years after a one-year pulse of present-day aviation emissions, SLCFs induce strong, but short-lived warming contributions to the GSAT response

ACCEPTED VERSION SUBJECT TO FINAL EDITING

(*medium confidence*), while CO_2 both gives a warming effect in the near term and dominates the long-term warming impact (*high-confidence*). {6.6.1, 6.6.2}

The effects of the SLCFs decay rapidly over the first few decades after pulse emission. Consequently, on time scales longer than about 30 years, the net long-term global temperature effects of sectors and regions are dominated by CO_2 (*high confidence*). The global mean temperature response following a climate mitigation measure that affects emissions of both short- and long-lived climate forcers depends on their atmospheric decay times, how fast and for how long the emissions are reduced, and the inertia in the climate system. For the SLCFs including methane, the rate of emissions drives the long-term global temperature effect, as opposed to CO_2 for which the long-term global temperature effect is controlled by the cumulative emissions. About 30 years or more after a one-year emission pulse occurs, the sectors contributing the most to global warming are industry, fossil fuel combustion for energy and land transportation, essentially through CO_2 (*high confidence*). Current emissions of SLCFs, CO_2 and N_2O from East Asia and North America are the largest regional contributors to additional net future warming on both short- (*medium confidence*) and long-time scales (*high confidence*). {6.6.1, 6.6.2}

At present, emissions from the residential and commercial sectors (fossil and biofuel use for cooking and heating) and the energy sector (fossil fuel production, distribution and combustion) contribute the most to the world population's exposure to anthropogenic fine PM (*high confidence*), whereas emissions from the energy and land transportation sectors contribute the most to ozone exposure (*medium to high confidence*). The contribution of different emission sectors to PM varies across regions, with the residential sector being the most important in South Asia and Africa, agricultural emissions dominating in Europe and North America, and industry and energy production dominating in Central and East Asia, Latin America and Middle East. Energy and industry are important $PM_{2.5}$ contributors in most regions, except Africa (*high confidence*). Source contributions to surface ozone concentrations are similar for all regions. {6.6.2}

Assuming implementation and efficient enforcement of both the Kigali Amendment to the Montreal Protocol on Ozone Depleting Substances and current national plans limit emissions (as in SSP1-2.6), the effects of HFCs on GSAT, relative to 2019, would remain below +0. 02°C from 2050 onwards versus about +0.04–0.08°C in 2050 and +0.1–0.3°C in 2100 considering only national HFC regulations decided prior to the Kigali Amendment (as in SSP5-8.5) (*medium confidence*). Further improvements in the efficiency of refrigeration and air-conditioning equipment during the transition to low-global-warming-potential refrigerants would bring additional GHG reductions (*medium confidence*) resulting in benefits for climate change mitigation and to a lesser extent for air quality due to reduced air pollutant emissions from power plants. {6.6.3, 6.7.3}

Future changes in SLCFs are expected to cause an additional warming. This warming is stable after 2040 in scenarios leading to lower global air pollution as long as methane emissions are also mitigated, but the overall warming induced by SLCF changes is higher in scenarios in which air quality continues to deteriorate (induced by growing fossil fuel use and limited air pollution control) (*high confidence*). If a strong air pollution control resulting in reductions in anthropogenic aerosols and non-methane ozone precursors was considered in SSP3-7.0, it would lead to a *likely* additional near-term global warming of 0.08 [0.00–0.10] °C in 2040. An additional concomitant methane mitigation (consistent with SSP1's stringent climate mitigation policy implemented in the SSP3 world) would not only alleviate this warming but would turn this into a cooling of 0.07 with a *likely* range of [-0.02 to 0.14] °C (compared with SSP3-7.0 in 2040). Across the SSPs, the collective reduction of CH_4, ozone precursors and HFCs can make a difference of GSAT of 0.2 with a *very likely* range of [0.1–0.4] °C in 2040 and 0.8 with a *very likely* range of [0.5–1.3] °C at the end of the 21st century (comparing SSP3-7.0 and SSP1-1.9), which is substantial in the context of the Paris Agreement. Sustained methane mitigation, wherever it occurs, stands out as an option that combines near- and long-term gains on surface temperature (*high confidence*) and leads to air quality benefits by reducing surface ozone levels globally (*high confidence*). {6.6.3, 6.7.3, 4.4.4}

Rapid decarbonization strategies lead to air quality improvements but are not sufficient to achieve, in the near term, air quality guidelines set for fine PM by the World Health Organization (WHO),

ACCEPTED VERSION SUBJECT TO FINAL EDITING

especially in parts of Asia and in some other highly polluted regions (*high confidence*). Additional CH_4 and BC mitigation would contribute to offsetting the additional warming associated with SO_2 reductions that would accompany decarbonization (*high confidence*). Strong air pollution control as well as strong climate change mitigation, implemented separately, lead to large reductions in exposure to air pollution by the end of the century (*high confidence*). Implementation of air pollution controls, relying on the deployment of existing technologies, leads more rapidly to air quality benefits than climate change mitigation, which requires systemic changes. However, in both cases, significant parts of the population are projected to remain exposed to air pollution exceeding the WHO guidelines. Additional policies envisaged to attain Sustainable Development Goals (SDG) (e.g., access to clean energy, waste management) bring complementary SLCF reduction. Only strategies integrating climate, air quality, and developments goals are found to effectively achieve multiple benefits. {6.6.3, 6.7.3, Box 6.2}

Implications of COVID-19 Restrictions for Emissions, Air Quality and Climate

Emissions reductions associated with COVID-19 containment led to a discernible temporary improvement of air quality in most regions, but changes to global and regional climate are undetectable above internal variability. Global anthropogenic NO_x emissions decreased by a maximum of about by 35% in April 2020 (*medium confidence*). There is *high confidence* that, with the exception of surface ozone, these emission reductions have contributed to improved air quality in most regions of the world. Global fossil CO_2 emissions decreased by 7% (with a range of 5.8% to 13.0%) in 2020 relative to 2019, largely due to reduced emissions from the transportation sector (*medium confidence*). Overall, the net ERF, relative to ongoing trends, from COVID-19 restrictions was likely small and positive for 2020 (less than 0.2 W m^{-2}), thus temporarily adding to the total anthropogenic climate influence, with positive forcing from aerosol changes dominating over negative forcings from CO_2, NO_x and contrail cirrus changes. Consistent with this small net radiative forcing, and against a large component of internal variability, Earth system model simulations show no detectable effect on global or regional surface temperature or precipitation (*high confidence*). {Cross-Chapter Box 6.1}

SUBJECT TO FINAL EDITING

6.1 Introduction

Short lived climate forcers (SLCFs) are a set of chemically and physically reactive compounds with atmospheric lifetimes typically shorter than two decades but differing in terms of physiochemical properties and environmental effects. SLCFs can be classified as direct or indirect, with direct SLCFs exerting climate effects through their radiative forcing and indirect SLCFs being precursors of direct climate forcers. Direct SLCFs include methane (CH_4), ozone (O_3), short lived halogenated compounds, such as hydrofluorocarbons (HFCs), hydrochlorofluorocarbons (HCFCs), and aerosols. Indirect SLCFs include nitrogen oxides (NO_x), carbon monoxide (CO), non-methane volatile organic compounds (NMVOCs), sulphur dioxide (SO_2), and ammonia (NH_3). Aerosols consist of sulphate (SO_4^{2-}), nitrate (NO_3^-), ammonium (NH_4^+), carbonaceous aerosols (e.g., black carbon (BC), organic aerosols (OA)), mineral dust, and sea spray (see Table 6.1) and can be present as internal or external mixtures and at sizes from nano-meters to tens of micro-meters. SLCFs can be emitted directly from natural systems and anthropogenic sources (primary) or can be formed by reactions in the atmosphere (secondary) (Figure 6.1).

6.1.1 Importance of SLCFs for climate and air quality

The atmospheric lifetime determines the spatial and temporal variability, with most SLCFs showing high variability, except CH_4 and many HCFCs and HFCs that are also well mixed (as a consequence CH_4 is discussed together with other well-mixed GHGs in Chapters 2, 5, and 7). In contrast to well-mixed greenhouse gases, such as CO_2, CH_4 and some HFCs, the radiative forcing effects of most of the SLCFs are largest at regional scales and climate effects predominantly occur in the first two decades after their emissions or formation. However, changes in their emissions can also induce long-term climate effects, for instance by altering some biogeochemical cycles. Therefore, the temporal evolution of radiative effects of SLCFs follows that of emissions, i.e., when SLCF emissions decline to zero their atmospheric abundance and radiative effects decline towards zero. The total influence of individual SLCF emissions on radiative forcing and climate account for their effects on the abundances of other forcers through chemistry (chemical adjustments).

SLCFs can affect climate by interacting with radiation or by perturbing other components of the climate system (e.g., the cryosphere and carbon cycle through deposition, or the water cycle through modifications of cloud properties via cloud condensation nuclei or ice nuclei). SLCFs can have either net warming or cooling effects on climate. In addition to altering the Earth's radiative balance, many SLCFs are also air pollutants with adverse effects on human health and ecosystems. SLCFs are of interest for climate policies (e.g., CH_4, HFCs), and are regulated as air pollutants (e.g., aerosols, O_3) or because of their deleterious influence on stratospheric ozone (e.g., HCFCs). The list of SLCFs assessed in this chapter and their effects are provided in Table 6.1.

[START FIGURE 6.1 HERE]

Figure 6.1: Sources and processes leading to atmospheric short-lived climate forcer (SLCF) burden and their interactions with the climate system. Both direct and indirect SLCFs and the role of atmospheric processes for the lifetime of SLCFs are depicted. Anthropogenic emission sectors illustrated are fossil fuel exploration, distribution and use, biofuel production and use, waste, transport, industry, agricultural sources, and open biomass burning. Emissions from natural systems include those from open biomass burning, vegetation, soil, oceans, lightning, and volcanoes. SLCFs interact with solar or terrestrial radiation, surface albedo, and cloud or precipitation system. The radiative forcing due to individual SLCF can be either positive or negative. Climate change induces changes in emissions from most natural systems as well as from some anthropogenic emission sectors (e.g. agriculture) leading to a climate feedback (purple arrows). Climate change also influences atmospheric chemistry processes, such as chemical reaction rates or via circulation changes, thus affecting atmospheric composition leading to a climate feedback. Air pollutants influence emissions from terrestrial vegetation, including agriculture (the grey arrow).

[END FIGURE 6.1 HERE]

[START TABLE 6.1 HERE]

Table 6.1: Overview of SLCFs of interest for Chapter 6. For each SLCF, its source types, lifetime in the atmosphere, and associated radiatively active agent is given. Source type can be primary (emitted from source categories) and/or secondary (formed through atmospheric oxidation mechanisms in the atmosphere). Unless otherwise noted, the stated lifetime refers to tropospheric lifetime*. Climate effect of increased SLCFs is indicated as "+" for warming and "-" for cooling. "Direct" is used for SLCFs exerting climate effects through their radiative forcing and "Indirect" for SLCFs which are precursors affecting the atmospheric burden of other climatically active compounds. Other processes through which SLCFs affect climate are listed where applicable. The World Health Organization (WHO) guidelines for air quality (AQ) are given, where applicable, to show which SLCFs are regulated for air quality purposes.

Compounds	**Source Type[a]**	**Lifetime**	**Direct**	**Indirect**	**Climate Forcing**	**Other effects on climate**	**WHO AQ guidelines[b]**
CH_4	Primary	~9 years ~12 years (perturbation time)	CH_4	O_3, H_2O, CO_2	+		No[c]
O_3	Secondary	Hours - weeks	O_3	CH_4, secondary organic aerosols, sulphates	+	Ecosystem	100 μg m^{-3} 8-hour mean
NO_x (= NO + NO_2)	Primary	Hours - days		O_3, nitrates, CH_4	+/-	Ecosystem	40 μg m^{-3} annual mean 200 μg m^{-3} 1-hour mean
CO	Primary + Secondary	1-4 months		O_3, CH_4	+		No
NMVOCs	Primary + Secondary	Hours - months		O_3, CH_4, organic aerosols	+/-		No
SO_2	Primary	Days (trop.) to weeks (strat.)		sulphates, nitrates, O_3	-		20 μg m^{-3} 24-hour mean 500 μg m^{-3} 10-minute mean
NH_3	Primary	Hours		Ammonium Sulphate, Ammonium Nitrate	-	Ecosystem	No
HCFCs	Primary	Months – years	HCFCs	Stratospheric O_3	+/-		No[c]
HFCs	Primary	Days – years	HFCs		+		No[c]
Halons and Methylbromide	Primary	Years	Halons and Methylbromide	Stratospheric O_3	+/-		No[c]
Very Short-Lived halogenated Species (VSLSs)	Primary	less than 0.5 year		Stratospheric O_3	-		No[c]
Sulphates	Secondary	Minutes – weeks	Sulphates		-	Cloud	as part of PM[d]
Nitrates	Secondary	Minutes – weeks	Nitrates		-	Cloud	as part of PM[d]
Carbonaceous aerosols	Primary + Secondary	Minutes to Weeks	BC, OA		+/ -	Cryo, Cloud	as part of PM[d]

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Sea spray	Primary	day to week	Sea spray		-	Cloud	as part of PM[d]
Mineral dust	Primary	Minutes to Weeks	Mineral dust		-	Cryo, Cloud	as part of PM[d]

[*] For lifetimes reported it in this table, it is assumed that the compounds are uniformly mixed throughout the troposphere, however, this assumption is unlikely for compounds with lifetimes < 1 year and therefore, the reported values should be viewed as approximations (Prather et al., 2001).
[a] Source types can be primary (emitted from source categories) and/or secondary (formed by reactions in the atmosphere). Cryo: effect on planetary albedo through deposition on snow and ice; [b] Krzyzanowski and Cohen (2008) ; [c] regulated through Kyoto/Montreal protocol; [d] For Particulate Matter with diameter < 2.5 µm ($PM_{2.5}$): 10 µg m^{-3} annual mean or 25 µg m^{-3} 24 hour mean (99th percentile) and for Particulate Matter with diameter < 10 µm (PM_{10}): 20 µg m^{-3} annual mean or 50 µ µg m^{-3} 24 hour mean (99th percentile)

[END TABLE 6.1 HERE]

As depicted in Figure 6.1, emissions of SLCFs are governed by anthropogenic activities and sources from natural systems (see Section 6.2 for details). Atmospheric chemistry in this context is both a source and a sink of SLCFs. For instance, O_3 and secondary aerosols are exclusively formed through atmospheric mechanisms (Section 6.3.2 and 6.3.5 respectively). The hydroxyl (OH) radical, the most important oxidizing agent in the troposphere, acts as a sink for SLCFs by reacting with them, and thereby, influencing their lifetime (Section 6.3.6). Through SLCF radiative forcing and feedbacks (see Section 6.4), key climate parameters, such as temperature, hydrological cycle, and weather patterns are perturbed. Climate change also influences air quality (Section 6.5). As depicted in Figure 6.1, SLCFs affect both climate and air quality, hence SLCF mitigation has linkages to both the issues (Section 6.6). Socio-economic narratives including air quality policies determine future projections of SLCFs in the five core Socioeconomic Pathways (SSPs): SSP1-1.9, SSP1-2.6, SSP2-4.5, SSP3-7.0, and SSP5-8.5 (described in Chapter 1), and in addition, a subset of SSP3 scenarios allows to isolate the effect of various SLCF mitigation trajectories on climate and air quality (Section 6.7).

6.1.2 Treatment of SLCFs in previous assessments

Although O_3, aerosols and their precursors have been considered in previous IPCC assessment reports, AR5 considered SLCFs as a specific category of climate relevant compounds but referred to them as near-term climate forcers (NTCFs) (Myhre et al., 2013). In AR5, the linkages between air quality and climate change were also considered in a more detailed and quantitative way than in previous reports (Kirtman et al., 2013; Myhre et al., 2013).

AR5 WGI assessed radiative forcings for short-lived gases, aerosols, aerosol precursors and aerosol cloud interactions (ERFaci) as well as the evolution of confidence level in the forcing mechanisms from SAR to AR5. Whereas the forcing mechanisms for ozone and aerosol-radiation interactions were estimated to be characterised with *high confidence*, the ones induced by aerosols through other processes remained of *very low* to *low confidence*. AR5 also reported that forcing agents such as aerosols and ozone changes are highly heterogeneous spatially and temporally and these patterns affect global and regional temperature responses as well as other aspects of climate response such as the hydrologic cycle (Myhre et al., 2013).

AR5 WGI also evaluated the air quality-climate interaction through the projected trends of surface O_3 and $PM_{2.5}$. Kirtman et al. (2013) concluded with *high confidence* that the response of air quality to climate-driven changes is more uncertain than the response to emission-driven changes, and also that locally higher surface temperatures in polluted regions will trigger regional feedbacks in chemistry and local emissions that will increase peak levels of O_3 and $PM_{2.5}$ (*medium confidence*).

In the Special Report on Global Warming of 1.5 °C (SR15)(Allen et al., 2018a), Rogelj et al., (2018a) state

ACCEPTED VERSION SUBJECT TO FINAL EDITING

that the evolution of CH_4 and SO_2 emissions strongly influences the chances of limiting warming to 1.5°C, and that, considering mitigation scenarios to limit warming to 1.5 or 2°C, a weakening of aerosol cooling would add to future warming in the near term, but can be tempered by reductions in methane emissions (*high confidence*). In addition, as some SLCFs are co-emitted alongside CO_2, especially in the energy and transport sectors, low CO_2 scenarios, relying on decline of fossil fuel use, can result in strong abatement of some cooling and warming SLCFs (Rogelj et al., 2018a).

On the other hand, specific reductions of the warming SLCFs (CH_4 and BC) would, in the short term, contribute significantly to the efforts of limiting warming to 1.5°C. Reductions of BC and CH_4 would have substantial co-benefits improving air quality and therefore limit effects on human health and agricultural yields. This would, in turn, enhance the institutional and socio-cultural feasibility of such actions in line with the United Nations' Sustainable Development Goals (Coninck et al., 2018).

Following SR15, the IPCC Special Report Climate Change and Land (SRCCL)(IPCC, 2019a) took into consideration the emissions on land of three major SLCFs: mineral dust, carbonaceous aerosols (BC and OA) and BVOCs (Jia et al., 2019). The SRCCL concluded that: i) there is no agreement about the direction of future changes in mineral dust emissions; ii) fossil fuel and biomass burning, and SOA from natural BVOC emissions are the main global sources of carbonaceous aerosols whose emissions are expected to increase in the near future due to possible increases in open biomass burning and increase in SOA from oxidation of BVOCs (*medium confidence*); iii) BVOCs are emitted in large amounts by forests and they are rapidly oxidised in the atmosphere to form less volatile compounds that can condense and form SOA, and in a warming planet, BVOC emissions are expected to increase but magnitude is unknown and will depend on future land use change, in addition to climate (*limited evidence, medium agreement*).

Finally, the IPCC Special Report on the Ocean and Cryosphere in a Changing Climate (SROCC)(IPCC, 2019b) discussed the effects of BC deposition on snow and glaciers, concluding that there is *high confidence* that darkening of snow through the deposition of BC and other light absorbing particles enhances snow melt in the Arctic (Meredith et al., 2019), but that there is *limited evidence* and *low agreement* that long-term changes in glacier mass of high mountain areas are linked to light absorbing particles (Hock et al., 2019).

6.1.3 Chapter Roadmap

Figure 6.2 presents the Chapter 6 roadmap.

Specific aspects of SLCFs can also be found in other chapters of this report: the evolution of ozone, HFCs, aerosols as well as long term evolution of methane, dust, volcanic aerosols are discussed in Chapter 2, near-term climate projections and SLCFs are discussed in Chapter 4, the global budget of methane is addressed in Chapter 5, aerosol-cloud and aerosol-precipitation interactions are treated in Chapters 7 and 8, respectively, the global radiative forcing of SLCFs is assessed in Chapter 7, some aspects of downscaling methodology in climate modelling concerning SLCFs are discussed in Chapter 10. The WGII report assesses how climate change affects air pollution and impacts on human health and the WGIII report assesses the role of SLCFs in abatement strategies and their cost effectiveness, the implications of mitigation efforts on air pollution as well as the articulation between air pollution policies and GHG mitigation.

This chapter discusses air quality from a global point of view with focus on surface ozone and particulate matter surface concentrations. Local and indoor air pollution, as well as effect of air pollution on health, are beyond the scope of this chapter. This assessment is mainly based on results and studies relying on global models or observation datasets operated through global networks or from satellites. Global chemistry-climate models allow to quantify the changes in background concentrations such as surface ozone due to large scale changes in climate or CH_4 by considering comprehensively the physiochemical processes (see Box 6.1). In addition, climate effects are often non-linear responses to concentrations which already respond non-linearly to emissions, with per mass unit effects often larger in pristine than in polluted regions, justifying the relevance of global models. However, specific aspects of urban air quality cannot be captured by global models and require high resolution modelling which reproduce the temporal and spatial variability of

ACCEPTED VERSION SUBJECT TO FINAL EDITING

emissions and abundances necessary to precisely account for the non-linearity of the chemistry and the sensitivity of local air pollution to its drivers. Consequently, the sectoral analysis in Section 6.6 and the mitigation effects in Section 6.7 cannot be directly applied for local air quality planning.

Due to their short lifetimes, SLCF trends and effects are strongly related to the localisation and evolution of the emission sources. To better link the drivers of emission evolution and SLCFs, Chapter 6 makes use of regions defined by the WGIII in most of the analysis. An exception is made for the effect of SLCFs on the climate, for which analysis relies on WGI Atlas regions.

[START FIGURE 6.2 HERE]

Figure 6.2: Chapter roadmap. See Section 6.1.3 for additional description of the chapter.

[END FIGURE 6.2 HERE]

6.2 Global and regional temporal evolution of SLCF emissions

SLCF emissions originate from a variety of sources driven by anthropogenic activities and natural processes. The natural sources include vegetation, soil, fire, lightning, volcanoes, and oceans. Changes in SLCF emissions from natural systems occur either due to human activities, such as land-use change, or due to global changes. Their sensitivity to climate change thus induces a climate feedback (see Section 6.4.6 for a quantification of these feedbacks). This section reviews the current understanding of historical emissions for anthropogenic, natural, and open biomass burning sources. A detailed discussion of methane sources, sinks, trends and their evaluation are provided in Chapter 5; Section 5.2.2.

6.2.1 Anthropogenic sources

Estimates of global anthropogenic SLCF emissions and their historical evolution that were used in AR5 (CMIP5) (Lamarque et al., 2010) have been revised for use in CMIP6 (Hoesly et al., 2018). The update considered new data and assessment of the impact of the environmental policies, primarily regarding air pollution control (Wang et al., 2014c, 2014b; Montzka et al., 2015; Crippa et al., 2016; Turnock et al., 2016; Klimont et al., 2017a; Zanatta et al., 2017; Prinn et al., 2018). Additionally, Hoesly et al. (2018) have extended estimates of anthropogenic emissions back to 1750 and developed an updated and new set of spatial proxies allowing for more differentiated (source sector-wise) gridding of emissions (Feng et al., 2020). The CMIP6 emission inventory has been developed with the Community Emissions Data System (CEDS) that improves upon existing inventories with a more consistent and reproducible methodology, similar to approaches used in, for example, EDGAR (Crippa et al., 2016) and GAINS model (Amann et al., 2011; Klimont et al., 2017b; Höglund-Isaksson et al., 2020) where emissions of all compounds are consistently estimated using the same emission drivers and propagating individual components (activity data and emission factors) separately to capture fuel and technology trends affecting emission trajectories over time. This contrasts the approach used to establish historical emissions for CMIP5 where different data sets available at the time were combined. The CMIP6 exercise is based on the first release of CEDS emission dataset (version 2017-05-18, sometimes referred to hereafter as CMIP6 emissions) whose main features regarding SLCFs are described hereafter. The CEDS has been and will be regularly updated and extended; the recent update of CEDS (Hoesly et al., 2019) and consequences for this assessment is discussed when necessary. Some details on how SLCF emissions have been represented in scenarios used by IPCC assessments can be found in Chapter 1 (see Chapter 1, Section 1.6.1 and Cross Chapter Box 1.4).

For most of the SLCF species, the global and regional anthropogenic emission trends developed for CMIP6 for the period 1850 to 2000 are not substantially different from those used in CMIP5 (Figures 6.18 & 6.19) despite the different method used to derive them. Hoesly et al. (2018, CEDS) developed an independent time series capturing trends in fuel use, technology, and level of control, whereas CMIP5 combined different

ACCEPTED VERSION SUBJECT TO FINAL EDITING

emission data sets. However, for the period after 1990, the CMIP6 dataset shows for all species, except for SO_2 and CO and since 2011 for NO_x, a different trend than CMIP5, i.e., continued strong growth of emissions driven primarily by developments in Asia (Figure 6.19). The unprecedented growth of East and South Asian emissions since 2000 changed the global landscape of emissions making Asia the dominant SLCF source region (Figures 6.3, 6.19). The Representative Concentration Pathways (RCP) scenarios used in AR5 started from the year 2000 (van Vuuren et al., 2011) and did not represent well the development of SLCF emissions until 2015. The CEDS inventory (Hoesly et al., 2018) includes improved representation of these trends and the estimate for 2014. These findings have been largely supported by several independent emission inventory studies and remote sensing data analysis, however, for the last decade the decline of Asian emissions of SO_2 and NO_x appears underestimated while growth of BC and OC emissions in Asia and Africa seems overestimated in CMIP6, compared to most recent regional evaluations (Klimont et al., 2017b; Zheng et al., 2018b; e.g., Elguindi et al., 2020; Kanaya et al., 2020; McDuffie et al., 2020), which are largely considered in the updated release of the CEDS (Hoesly et al., 2019). Consequently, global CMIP6 anthropogenic emissions for 2015 are likely overestimated by about 10% for SO_2 and NO_x and about 15% for BC and OC.

For SO_2, independent emission inventories and observational evidence show that on a global scale strong growth of Asian emissions has been countered by reduction in North America and Europe (Reis et al., 2012; Amann et al., 2013; Crippa et al., 2016; Aas et al., 2019). Since about 2006, also Chinese emissions declined by nearly 70% by 2017 (Silver et al., 2018; Zheng et al., 2018b; Mortier et al., 2020; Tong et al., 2020) (*high confidence*). The estimated reduction in China contrasts continuing strong growth of SO_2 emissions in South Asia (Figure 6.19). In 2014, over 80% of anthropogenic SO_2 emissions originated from power plants and industry with Asian sources contributing more than 50% of total (Figure 6.3).

Global emissions of NO_x have been growing in spite of the successful reduction of emissions in North America, Europe, Japan, Korea (Crippa et al., 2016; Turnock et al., 2016; Miyazaki et al., 2017; Jiang et al., 2018a) partly driven by continuous efforts to strengthen the emission standards for road vehicles in most countries (Figure 6.18 & 6.19). In many regions, an increase in vehicle fleet as well as non-compliance with emission standards (Anenberg et al., 2017, 2019; Jonson et al., 2017; Jiang et al., 2018a), growing aviation (Grewe et al., 2019; Lee et al., 2021) and demand for energy, and consequently large number of new fossil fuel power plants, have been overcompensating these reductions. Since about 2011, global NO_x emissions appear to have stabilized or slightly declined (*medium confidence*) but the global rate of decline has been underestimated in CEDS, as recent data suggest that emission reductions in China were larger than included in CEDs. (Figure 6.19 and Hoesly et al. (2018)). Recent bottom up emission estimates (Zheng et al., 2018b) largely confirm what has been shown in satellite data (Liu et al., 2016a; Miyazaki et al., 2017; Silver et al., 2018); a strong decline of NO_2 column over Eastern China (*high confidence*) (see Section 6.3.3.1). At a global level, the estimated CEDS CO emission trends are comparable to NO_x, which has been confirmed by several inverse modelling studies (see Section 6.3.3.2). Transport sector (including international shipping and aviation) was the largest anthropogenic source of NO_x (about 50% of total) and contributed also over 25% of CO emissions in 2014, and Asia represented half and North America and Europe about 20% of global total NO_x and CO (Figure 6.3).

Oil production-distribution and transport sector have dominated anthropogenic NMVOC emissions for most of the 20th century (Hoesly et al., 2018) and still represent a large share (Figure 6.3). Efforts to control transport emissions (i.e. increasing stringency of vehicle emission limits) were largely offset by fast growth of emissions from chemical industries and solvent use as well as from fossil fuel production and distribution, resulting in continued growth of global anthropogenic NMVOC emissions since 1900 (Figure 6.18) (*high confidence)*. Since AR5, there is *high confidence* that motor vehicle NMVOC emissions have sharply decreased in North America and Europe in the last decades (Rossabi and Helmig, 2018), i.e., by about an order of magnitude in major U.S. cities since 1990 (Bishop and Haugen, 2018; McDonald et al., 2018). Increasing (since 2008) oil and gas extraction activities in North America lead to a strong growth of NMVOC emissions (*high confidence*) as shown by analysis of ethane columns data (Franco et al., 2016), but absolute emission amounts remain uncertain (Pétron et al., 2014; Tzompa-Sosa et al., 2019). In East Asia, there is *medium confidence* in a decreasing trend of motor vehicle emissions, suggested by ambient measurements in Beijing since 2002 (Wang et al., 2015) and by bottom-up estimates (Zheng et al., 2018b),

ACCEPTED VERSION SUBJECT TO FINAL EDITING

and decrease of residential heating emissions due to declining coal and biofuel use since 2005 (Zheng et al., 2018b; Li et al., 2019b). However, total anthropogenic NMVOC emissions have increased steadily in China since the mid-20th century, largely due to growing importance of the solvent use and industrial sectors (Sun et al., 2018; Zheng et al., 2018b; Li et al., 2019b) (*medium evidence, high agreement*). Resulting changes in the NMVOC speciated emissions might be underestimated in the current regional and global inventories. For example, in the U.S., a recent study suggested an emergent shift in urban NMVOC sources from transportation to chemical products (i.e. household chemicals, personal care products, solvents, etc.), which is not in accordance with emission inventories currently used (McDonald et al., 2018). In many European regions and cities, wood burning has been increasingly used for residential heating, partly for economic reasons and because it is considered CO_2-neutral (Athanasopoulou et al., 2017); in situ measurements in several cities, including Paris, suggest that wood burning explains up to half the NMVOC emissions during winter (Kaltsonoudis et al., 2016; Languille et al., 2020). Due to the vast heterogeneity of sources and components of VOCs, uncertainty in regional emissions and trends is higher than for most other components.

Emissions of carbonaceous aerosols (BC, OC) have been steadily increasing and their emissions have almost doubled since 1950 (Hoesly et al., 2018) (*medium confidence*). Before 1950, North America and Europe contributed about half of the global total but successful introduction of diesel particulate filters on road vehicles (Fiebig et al., 2014; Robinson et al., 2015; Klimont et al., 2017a) and declining reliance on solid fuels for heating brought in large reductions (Figure 6.19) (*high confidence*). Currently, global carbonaceous aerosol emissions originate primarily from Asia and Africa (Bond et al., 2013; Hoesly et al., 2018; Elguindi et al., 2020; McDuffie et al., 2020), representing about 80% of global total (Figure 6.3) (*high confidence*). Consideration, in CMIP6, of emissions from kerosene lamps and gas flaring, revised estimates for open burning of waste, regional coal consumption, and new estimates for Russia (Stohl et al., 2013; Huang et al., 2015; Huang and Fu, 2016; Kholod et al., 2016; Conrad and Johnson, 2017; Evans et al., 2017; Klimont et al., 2017a) resulted in over 15% higher global emissions of OC and BC than in the CMIP5 estimates for the first decade of the 21st Century (Figure 6.18). The continued increase of BC emissions over East Asia after 2005, estimated in CMIP6 (Figure 6.19), has been, however, questioned recently as a steady decline of BC concentrations was measured in the air masses flowing out from east coast of China (Kanaya et al., 2020), which has been also estimated in recent regional bottom-up and top-down inventories (Zheng et al., 2018a; Elguindi et al., 2020; McDuffie et al., 2020). Since AR5, confidence in emission estimates and trends in North America and Europe has increased but high uncertainties remain for Asia and Africa that dominate global emissions. Size distribution of emitted species, of importance for climate and health impacts, remains uncertain and CEDS inventory does not provide such information. Overall, a factor two uncertainty in global estimates of BC and OC emissions remains, with post 2005 emissions overestimated in Asia (*high confidence*) and Africa (*medium confidence*).

Bottom up global emission estimates of CH_4 (Lamarque et al., 2010; Hoesly et al., 2018; Janssens-Maenhout et al., 2019; Höglund-Isaksson et al., 2020) for the last two decades are higher than top down assessments (e.g., Saunois et al., 2016, 2020) but trends from the two methods are similar and indicate continued growth (*high confidence*). Larger discrepancies exist at the sectoral and regional levels, notably for coal mining (Peng et al., 2016; Miller et al., 2019) and oil and gas sector due to growth of unconventional production and higher loss estimates (Franco et al., 2016; Alvarez et al., 2018; Dalsøren et al., 2018) (see also Section 5.2.2).

Agricultural production (livestock and mineral nitrogen fertilizer application) is the primarily source of ammonia in the atmosphere with more than half of present day emissions originating in Asia (Hoesly et al., 2018; Figure 6.3, EC-JRC / PBL, 2020; Vira et al., 2020). NH_3 emissions are estimated to have grown strongly since 1850, especially since 1950 driven by continuously increasing livestock production, widespread application of mineral nitrogen fertilizers and lack of action to control ammonia (Erisman et al., 2008; Riddick et al., 2016; Hoesly et al., 2018; Fowler et al., 2020) (*high confidence*). The trends estimated in CMIP5 and CMIP6 are similar, while in absolute terms CMIP6 has somewhat higher emissions as it includes emissions from wastewater and human waste that were largely missing in CMIP5 (Hoesly et al., 2018). CMIP6 has improved spatial and temporal distribution of emissions (e.g., Lamarque et al., 2013a) relying on the EDGAR v4.3 and Paulot et al. (2014), but important uncertainties remain for regionally-specific temporal patterns (Riddick et al., 2016; Liu et al., 2019; Feng et al., 2020; Vira et al., 2020). The continuing increase in global NH_3 emissions is driven primarily by growing livestock and crop production in

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Asia while emissions in the US and Europe remain about constant or slightly decline in the last decade (Hoesly et al., 2018). Recent satellite and ground observations support trends estimated in CMIP6 dataset (Section 6.3.3.4).

To summarize, there are significant differences in spatial and temporal emission patterns of SLCFs across global regions (Figure 6.18). Until the 1950s, the majority of SLCF emissions associated with fossil fuel use (SO_2, NO_x, NMVOCs, CO) and about half of BC and OC originated from North America and Europe (Lamarque et al., 2010; Hoesly et al., 2018). Since the 1990s a large redistribution of emission was associated with strong economic growth in Asia and declining emissions in North America and Europe due to air quality legislation and declining capacity of energy intensive industry, and currently more than 50% of anthropogenic emissions of each SLCF species (including CH_4 and NH_3) originates from Asia (Amann et al., 2013; Bond et al., 2013; Fiore et al., 2015; Crippa et al., 2016, 2018; Klimont et al., 2017a; Hoesly et al., 2018) (Figure 6.3). The dominance of Asia for SLCF emissions is corroborated by growing remote sensing capacity that has been providing independent evaluation of estimated pollution trends in the last decade (Duncan et al., 2013; Lamsal et al., 2015; Luo et al., 2015; Fioletov et al., 2016; Geddes et al., 2016; Irie et al., 2016; Krotkov et al., 2016; Wen et al., 2018).

Since AR5, the quality and completeness of activity and emission factor data and applied methodology, including spatial allocation together with independent satellite-derived observations, have improved, raising confidence in methods used to derive emissions. There is *high confidence* in the sign of global trends of SLCF emissions until the year 2000. However, only *medium confidence* for the rate of change in the two last decades owing primarily to uncertainties in actual application of reduction technologies in fast growing economies of Asia. At a regional level, bottom-up derived SLCF emission trends and magnitudes in regions with strong economic growth and changing air quality regulation are highly uncertain and better constrained with top-down methods (Section 6.3). For most SLCF species, there is *high confidence* in trends and magnitudes for affluent OECD regions where accurate and detailed information about drivers of emissions exists; *medium* confidence is assessed for regional emissions of NH_3, CH_4 and NMVOC.

[START FIGURE 6.3 HERE]

Figure 6.3: Relative regional and sectoral contributions to the present day (year 2014) anthropogenic emissions of Short Lived Climate Forcers (SLCFs). Emission data are from the Community Emissions Data System (CEDS) (Hoesly et al., 2018). Emissions are aggregated into the following sectors: fossil fuel production and distribution (coal mining, oil and gas production, upstream gas flaring, gas distribution networks), fossil fuel combustion for energy (power plants), residential and commercial (fossil and biofuel use for cooking and heating), industry (combustion and production processes, solvent use loses from production and end use), land transportation (road and off-road vehicles), shipping (including international shipping), aviation (including international aviation), agriculture (livestock and crop production), waste management (solid waste, including landfills and open trash burning, residential and industrial waste water), and other. Further details on data sources and processing are available in the chapter data table (Table 6.SM.1).

[END FIGURE 6.3 HERE]

6.2.2 Emissions by natural systems

This section assesses our current understanding of SLCF emissions by natural systems. Many naturally occurring emission processes in the Earth System have been perturbed by the growing influence of human activities either directly (e.g., deforestation, agriculture) or via human-induced atmospheric CO_2 increase and climate change and can therefore not be considered as purely natural emissions. The temporal evolution and spatial distribution of natural SLCF emissions are highly variable and their estimates rely on models with rather uncertain parameterizations for production mechanisms. For some SLCFs, the natural processes by which emissions occur are also not well-understood. In the following sections, we assess the level of confidence in present-day SLCF emissions by natural systems, in their perturbation since preindustrial and

ACCEPTED VERSION SUBJECT TO FINAL EDITING

their sensitivity to future changes. When available, the assessment also includes estimates from CMIP6 model ensemble. Note that volcanic SO_2 emissions are discussed in Section 2.2.2.

6.2.2.1 Lightning NO_x

Lightning contributes ~10% of the total NO_x emissions (Murray, 2016). Since lightning NO_x (LNO_x) is predominantly released in the upper troposphere, it has a disproportionately large impact on O_3 and OH, and on the lifetime of CH_4 compared with surface NO_x emissions. Whereas the global spatial and temporal distribution of lightning flashes can be characterized thanks to satellite-borne and ground sensors (DuplicateVirts, 2013; Cecil et al., 2014), constraining the amount of NO_x produced per flash (Miyazaki et al., 2014; Medici et al., 2017; Nault et al., 2017; Marais et al., 2018; Allen et al., 2019a; Bucsela et al., 2019) and its vertical allocation (Koshak et al., 2014; Medici et al., 2017) has been more elusive. Atmospheric Chemistry and Climate Model Intercomparison Project (ACCMIP) models in CMIP5 used a range of LNO_x between 1.2 to 9.7 TgN $year^{-1}$ (Lamarque et al., 2013c). In CMIP6, the corresponding LNO_x range is between 3.2 to 7.6 TgN $year^{-1}$ (Griffiths et al., 2020). All CMIP6 models (as well as most models included in the CMIP5, Young et al., 2013) apply a parameterization that relates cloud-top-height to lightning intensity (Price and Rind, 1992), projecting an increase in LNO_x in a warmer world in the range 0.27 to 0.61 Tg(N) yr^{-1} per °C (Thornhill et al., 2021a). However, models using parameterizations based on convection (Grewe et al., 2001), updraft mass flux (Allen and Pickering, 2002), or ice flux (Finney et al., 2016a) show either much less sensitivity or a negative response (Finney et al., 2016b, 2018; Clark et al., 2017).
In summary, the total present-day global lightning NO_x emissions are still estimated to be within a factor of 2. There is *high confidence* that LNO_x are perturbed by climate change however there is *low confidence* in the sign of the change due to fundamental uncertainties in parameterizations.

6.2.2.2 NO_x emissions by soils

Soil NO_x (SNO_x) emissions occur in connection with complex biogenic/microbial nitrification and denitrification processes (Ciais et al., 2013), which in turn are sensitive – in a non-linear manner – to temperature, precipitation, soil moisture, carbon and nutrient content and the biome itself (e.g., Hudman et al., 2012). Global SNO_x estimates, based on observationally constrained chemistry-transport model and vegetation model studies, show a broad range between 4.7 and 16.8 TgN/yr (Young et al., 2018). This estimate is generally larger than the current source strength used in CMIP6 simulations, which is prescribed using an early empirical estimate, typically scaled to about 5 TgN/yr (Yienger and Levy, 1995)
Under warmer climate, the overall nitrogen fixation in non-agricultural ecosystems is expected to be 40% larger than in 2000, due to increased enzyme activity with growing temperatures, but the emission rates of NO (and N_2O) is expected to be dominated by changes in precipitation patterns and evapotranspiration fluxes (Fowler et al., 2015). Current earth system models (ESM) incorporate biophysical and biogeochemical processes only to a limited extent (Jia et al., 2019), precluding adequate climate sensitivity studies for SNO_x. Hence, while the current strength source of soil NO_x has been better constrained over the last decade, adequate representations of SNO_x and how it escapes from the canopy are still missing in ESM to provide quantitative estimates of climate driven changes in SNO_x.

6.2.2.3 Vegetation emissions of organic compounds

A wide range of BVOCs are emitted from vegetation with the dominant compounds being isoprene and monoterpenes but also including sesquiterpenes, alkenes, alcohols, aldehydes and ketones. The photo-oxidation of BVOC emissions plays a fundamental role in atmospheric composition by controlling the regional and global budgets of ozone and organic aerosols, and impacting the lifetime of methane and other reactive components (Arneth et al., 2010b; Heald and Spracklen, 2015). Substantial uncertainty exists across different modelling frameworks for estimates of global total BVOC emissions and individual compound emissions (Messina et al., 2016). Global isoprene emission estimates differ by a factor of 2 from 300-600 Tg(C) yr^{-1} and global monoterpene emission estimates by a factor of 5 from 30-150 Tg(C) yr^{-1} (Messina et al., 2016). A main driver of the uncertainty ranges is the choice of assignment of PFT-specific basal emission

ACCEPTED VERSION SUBJECT TO FINAL EDITING

rates in the model, however, the smaller uncertainty range for isoprene than for monoterpenes is not fully understood (Arneth et al., 2008). The evaluation of global BVOC emissions is challenging because of poor measurement data coverage in many regions and the lack of year-round measurements (Unger et al., 2013). Several observational approaches have been developed in the past few years to improve understanding of BVOC emissions including indirect methods such as the measurement of the OH loss rate in forested environments (Yang et al., 2016) and application of the variability in satellite formaldehyde concentrations (Palmer et al., 2006; Barkley et al., 2013; Stavrakou et al., 2014). Direct space-borne isoprene retrievals using infrared (IR) radiance measurements have very recently become available (Fu et al., 2019; Wells et al., 2020). Collectively these approaches have identified weaknesses in the ability of the parameterizations in global models to reproduce BVOC emissions hotspots (Wells et al., 2020). However, none of the current observational approaches have yet been able to reduce the uncertainty ranges in global emission estimates.

At the plant level, BVOC emission rates and composition depend strongly on plant species with plants tending to emit either isoprene or monoterpenes but not both. Photosynthetic activity is a main driver of isoprene and monoterpene production. Therefore, radiation and temperature, along with leaf water status, phenological state and atmospheric CO_2 mixing ratio, affect emissions directly (on the leaf-scale) and indirectly (via plant productivity) (Guenther et al., 2012; Loreto et al., 2014; Niinemets et al., 2014). CO_2 directly influences the isoprene synthesis process, with inhibition under increasing atmospheric CO_2 (Rosenstiel et al., 2003; Possell et al., 2005; Wilkinson et al., 2009). Direct CO_2 inhibition has been observed for some monoterpene compounds (Loreto et al., 2001; Llorens et al., 2009). Severe/long-term water stress may reduce emissions whilst mild/short-term water stress may temporarily amplify or maintain BVOC emissions to protect plants against on-going stress (Peñuelas and Staudt, 2010; Potosnak et al., 2014; Genard-Zielinski et al., 2018). Furthermore, observations in the Amazon, indicate the chemical composition of monoterpene emissions could also change under elevated temperature conditions (Jardine et al., 2016). In addition, all these processes are investigated over short-time scales but the long-term response of BVOC emissions depends on how the vegetation itself responds to the altered climate state (including temperature and water stress).

Global BVOC emissions are highly sensitive to environmental change including changes in climate, atmospheric CO_2 and vegetation composition and cover changes in natural and managed lands. Recent global modelling studies agree that global isoprene emissions have declined since the preindustrial driven predominantly by anthropogenic LULCC with results converging on a 10-25% loss of isoprene emissions globally between 1850 and present day (Lathière et al., 2010; Unger, 2013, 2014; Acosta Navarro et al., 2014; Heald and Geddes, 2016a; Hantson et al., 2017; Hollaway et al., 2017; Scott et al., 2017). The historical evolution of monoterpene and sesquiterpene emissions is less well studied and there is no robust consensus on even the sign of the change (Acosta Navarro et al., 2014; Hantson et al., 2017). Future global isoprene and monoterpene emissions depend strongly on the climate and land-use scenarios considered (Hantson et al., 2017; Szogs et al., 2017). BVOC emissions will be sensitive to future land-based climate change mitigation strategies including afforestation and bioenergy, with impacts of bioenergy depending on the choice of crops (Szogs et al., 2017).

Most CMIP6 models use overly simplistic parameterizations and project an increase in global BVOC emissions in response to warming temperatures (Turnock et al., 2020). This good agreement actually reflects the lack of diversity in BVOC emission parametrizations in global models that do not fully account for the complex processes influencing emissions discussed above.

Overall, we assess that historical global isoprene emissions declined between the preindustrial and present day by 10-25% *low confidence*) but historical changes in global monoterpenes and sesquiterpenes are too uncertain to provide an assessment. Future changes in BVOCs depend strongly on the evolution of climate and land-use and are strongly sensitive to land-based climate change mitigation strategies. However, the net response of BVOC emissions is uncertain due to complexity of processes, hard to constrain observationally, considered with various degrees of details in models.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

6.2.2.4 Land emissions of dust particles

The emission of dust particles into the atmosphere results from a natural process, namely saltation bombardment of the soil by large wind-blown particles such as sand grains and from disintegration of saltating particle clusters (Kok et al., 2012). The occurrence and intensity of dust emissions are controlled by soil properties, vegetation, and near-surface wind, making dust emissions sensitive to changes in climate, and land-use and land cover (Jia et al., 2019). In addition, dust can be directly emitted through human activities, such as agriculture, off-road vehicles, building construction, mining, and indirectly emitted through hydrological changes due to human actions such water diversion for irrigation (e.g. Ginoux et al., 2012). Estimates of the anthropogenic fraction of global dust vary from less than 10% to over 60% suggesting that human contribution to the global dust budget is quite uncertain (Ginoux et al., 2012; Stanelle et al., 2014; Xi and Sokolik, 2016). Reconstruction of global dust (deposition) from paleo records indicate factor of 2 to 4 changes between the different climate regimes in the glacial and interglacial periods (see Section 2.2.6). An extremely limited number of studies have explored the evolution of global dust sources since preindustrial times (Mahowald et al., 2010; Stanelle et al., 2014). A modelling study estimated a 25% increase in global dust emissions between the late nineteenth century to present due to agricultural land expansion and climate change (Stanelle et al., 2014). CMIP5 models were unable to capture the observed variability of annual and longer time scales in North African dust emissions (Evan et al., 2014), however more recent ESMs with process-based dust emission schemes that account for changes in vegetation and climate in a more consistent manner better match the observations (Kok et al., 2014; Evans et al., 2016). Feedbacks between the global dust cycle and the climate system (see Section 6.4.6) could account for a substantial fraction of the total aerosol feedbacks in the climate system with an order of magnitude enhancement on regional scale (Kok et al., 2018). In summary, there is *high confidence* that atmospheric dust source and loading are sensitive to changes in climate and land use, however, there is *low confidence* in quantitative estimates of dust emission response to climate change.

6.2.2.5 Oceanic emissions of marine aerosols and precursors

Oceans are a significant source of marine aerosols that influence climate directly by scattering and absorbing solar radiation or indirectly through the formation of cloud condensation nuclei (CCN) and ice nucleating particles (INP). Marine aerosols consist of primary sea spray particles and secondary aerosols produced by the oxidation of emitted precursors, such as dimethylsulphide (DMS) and numerous other BVOCs. Sea spray particles, composed of sea-salt and primary organic aerosols (POA), are produced by wind induced wave breaking as well as direct mechanical disruption of waves. The understanding of sea spray emissions has increased substantially over the last five years, however, the knowledge of formation pathways and factors influencing their emissions continue to have large uncertainties (Forestieri et al., 2018; Saliba et al., 2019). The emission rate of sea-spray particles is predominantly controlled by wind speed. Since AR5, the influence of other factors, including sea surface temperature, wave history and salinity is increasingly evident (Callaghan et al., 2014; Grythe et al., 2014; Ovadnevaite et al., 2014; Salter et al., 2014; Barthel et al., 2019). Marine POA, often the dominant submicron component of sea spray, are emitted as a result of oceanic biological activity, however the biological processes by which these particles are produced remain poorly characterized contributing to large uncertainties in global marine POA emission estimates (Tsigaridis et al., 2014; Burrows et al., 2018; Cravigan et al., 2020; Hodzic et al., 2020). Furthermore, particle size and chemical composition of sea spray particles and how these evolve in response to changing climate factors and dynamic oceanic biology continue to have large uncertainties.

DMS, the largest natural source of sulphur in the atmosphere, is produced by marine phytoplankton and is transferred from ocean water to the atmosphere due to wind-induced mixing of surface water. DMS oxidizes to produce sulphate aerosols and contributes to the formation of CCN. Since AR5, the range in global DMS flux estimates reduced from 10-40 Tg S $year^{-1}$ to 9 to 34 Tg S $year^{-1}$ with a *very likely* range of 18-24 Tg S $year^{-1}$ based on sea-surface measurements and satellite observations (Lana et al., 2011). DMS production, and consequently emissions, have been shown to respond to multiple stressors, including climate warming, eutrophication, and ocean acidification. However, large uncertainties in process-based understanding of the mechanisms controlling DMS emissions, from physiological to ecological, limit our knowledge of past

ACCEPTED VERSION SUBJECT TO FINAL EDITING

variations and our capacity to predict future changes.

Overall, there is *low confidence* in the magnitude and changes in marine aerosol emissions in response to shifts in climate and marine ecosystem processes.

6.2.2.6 Open biomass burning emissions

Open biomass burning (including forest, grassland, peat fires and agricultural waste burning) represent about 30%, 10%, 15% and 40% of present-day global emissions of CO, NO_x, BC, and OC, respectively (van Marle et al., 2017; Hoesly et al., 2018). Wildfires also play an important role in several atmospheric chemistry–climate feedback mechanisms (Bowman et al., 2009; Fiore et al., 2012) and fire events occurring near populated areas induce severe air pollution episodes (Marlier et al., 2020; Rooney et al., 2020; Yu et al., 2020).

For the last two decades, model-based emission estimates are constrained by remote sensing capacity to detect active fires and area burned. In AR5, biomass burning emissions were derived from a satellite product (Lamarque et al., 2010). Since then, improvements in detection of small fires has enhanced the agreement with higher-resolution and ground-based data on burned area in several regions (Randerson et al., 2012; Mangeon et al., 2015) especially for areas subjected to agricultural waste burning (Chuvieco et al., 2016, 2019). The updated emission factors and contribution of forest versus savannah fires lead to significantly higher global emissions of NO_x and lower emissions of OC and CO in CMIP6, compared with CMIP5. A recent compilation and assessment of emission factors (Andreae, 2019) indicates that the emission factors from Akagi et al. (2011), primarily used to produce the CMIP6 datasets, differ within ±50% for CO, OC, BC, and NO_x, depending on the biome, and would imply, for example, up to 10-30% higher OC and BC emissions from tropical forest fires.

The historical (pre-satellite era) dataset for CMIP6 considers advances in knowledge of past fire dynamics (new fire proxy datasets, such as charcoal in sediments or levoglucosan in ice-cores) and visibility records from weather stations (Marlon et al., 2016; van Marle et al., 2017). At a global level, CMIP5 and CMIP6 emission trends are similar, however, there are substantial differences at the regional level, especially for the United States, South America (south of Amazonia), and southern hemisphere Africa (van Marle et al., 2017).

Globally, the CMIP5 estimates (Lamarque et al., 2010), indicated gradual decline of open biomass burning emission from 1920 to about 1950 and then steady, and stronger than CMIP6, increase towards 2000. In contrast, CMIP6 biomass burning emissions (van Marle et al., 2017) increase only slightly over 1750 to 2015 and peak during the 1990s after which they decrease gradually consistently, with the assessment of fire trends in Chapter 5. Therefore, the CMIP6 evolution has a smaller difference between pre-industrial and present emissions than CMIP5, resulting in a lower radiative forcing of biomass burning SLCFs, leading to possibly lower effect on climate (van Marle et al., 2017).

Climate warming, especially through change in temperature and precipitation, will generally increase the risk of fire (Jia et al., 2019, see also Chapter 12) and can also affect the fire injection and plume height (Veira et al., 2016), but occurrence of fires and their emissions in the future strongly depends on anthropogenic factors such as population density, land use and fire management (Veira et al., 2016). Consequently, future emissions vary widely with increases and decreases amongst the SSP scenarios due to different land use change scenarios.

In summary, there has been an improvement in the knowledge of biomass burning emissions by reducing key uncertainties highlighted in AR5. However, systematic assessment of remaining uncertainties is limited, with a lower limit of uncertainties due to emission factors of 30 %, and larger uncertainties due to burning activity estimates, especially at regional level. Overall, a *medium confidence* in current global biomass burning SLCF emissions and their evolution over the satellite era is assessed. There is *low*-to-*medium confidence* in pre-industrial to the 1980s of biomass SLCF emissions, which rely on incorporation of several proxy data, with limited spatial representativeness. Nevertheless, uncertainties in absolute value of pre-

ACCEPTED VERSION SUBJECT TO FINAL EDITING

industrial emissions remain high, limiting confidence of radiative forcing estimates.

6.3 Evolution of Atmospheric SLCF abundances

This section assesses the evolution of atmospheric abundance[1] of SLCFs since AR5 based on observations and modelling, our knowledge of SLCFs burden and distribution, and our understanding of the trends over longer time scales. In addition to emissions (section 6.2), atmospheric chemistry (gas and aqueous chemistry), deposition (including wet and dry removal), and transport processes play a major role in determining the atmospheric distribution, budget and lifetime of SLCFs. The distribution and lifetime of SLCFs are further influenced by the modulation of chemical and physical processes in response to a changing climate. Therefore, the time evolution of atmospheric abundance of SLCFs is characterized by many complex non-linear interactions occurring at varying temporal and spatial scales. For this assessment, global scale, long-term measurements are employed only for a few gaseous SLCFs while for most short-lived species regional-scale observations and global models are relied upon.

[START BOX 6.1 HERE]

BOX 6.1: Atmospheric abundance of SLCFs: from process level studies to global chemistry-climate models

Changes in the atmospheric distribution of SLCFs determine their radiative forcing, and climate and air quality impacts. This box provides an overview of how process level understanding of the distribution and evolution of chemical compounds is derived and where uncertainties come from.

Process-level understanding of tropospheric gas and aerosol chemistry developed through laboratory and simulation chamber experiments as well as quantum chemical theory is used to generate chemical mechanisms. Atmospheric simulation chambers are designed to identify the chemical pathways and quantify reaction kinetics in isolation from atmospheric transport, deposition and emission processes. Ideally the chemical regimes studied, are representative for ambient atmospheric complexity and concentrations (e.g., McFiggans et al., 2019). Recently, quantum chemical theory has advanced to a level that it can provide kinetic and product information in a parameter range not possible with laboratory experiments (Vereecken et al., 2015). Iterative and interlinked use of simulation chamber and quantum chemical theory has led to improved knowledge of chemical mechanisms (Fuchs et al., 2013a; Nguyen et al., 2010; Peeters et al., 2009, 2014). For application in chemistry climate models (CCMs), the chemical mechanisms need to be computationally efficient, requiring simplifications. Such simplifications include reduced hydrocarbon representations, the application of lumping techniques (one compound or a chemical structure representing a family of compounds, for example, as done for parameterizing SOA formation) and/or the implementation of artificial operators representing key steps of the chemistry (Emmerson and Evans, 2009; Xia et al., 2009; Stockwell et al., 2020). Additionally, aerosol microphysical processes (nucleation, coagulation, condensation, evaporation, and sedimentation) that determine the evolution of aerosol number concentrations and size particle distribution are represented in parameterised forms in global models with varying levels of complexity (Mann et al., 2014).

A wide range of in situ and remotely sensed observations are used to characterise atmospheric chemical composition. Measurements made routinely as part of long-term monitoring programmes are particularly useful for assessing long-term trends and variability, and spatial distributions (as in Section 2.2, Section 6.3, and Section 7.3.3) while intensive field campaigns provide a more comprehensive view of atmospheric composition at a specific location for a limited time facilitating an improved process-level understanding. Retrieval of atmospheric concentrations from satellites, in particular, has been tremendously useful for providing global continuous coverage, although the retrievals themselves depend on prior information of atmospheric composition usually derived from models. Over the last decade or so, observations of

[1] The word ‘concentration’ is used to denote abundances in terms of mixing ratio for most species unless specified

ACCEPTED VERSION SUBJECT TO FINAL EDITING

atmospheric concentrations have been combined with information from global chemistry-climate models to produce global assimilation and forecasting systems with the purpose of producing chemical reanalysis or improving model inputs (i.e., emissions or boundary conditions) and forecasts (Miyazaki et al., 2015; Randles et al., 2017; Inness et al., 2019).

Global three-dimensional CCMs (Box 6.1, Figure 1) represent the full coupling of chemistry with climate physics (e.g., Morgenstern et al. 2017) with different levels of complexity (e.g, interactive aerosols with or without tropospheric and/or stratospheric chemistry). Methane concentrations are typically prescribed or constrained to observations while emissions of other SLCFs (or their precursors) are either prescribed or calculated interactively in the current generation of CCMs (Collins et al., 2017). CCMs, now part of Earth System Models (ESMs), are applied extensively to simulate the distribution and evolution of chemical compounds on a variety of spatial and temporal scales to improve current knowledge, make future projections and investigate global scale chemistry-climate interactions and feedbacks (see also Chapter 3 Section 3.8.2.2). CCMs are also used to interpret observations to disentangle the processes that drive observed variability and trends. Some aspects of air quality, such as diurnal peaks or local threshold violations, strong gradient in chemical regimes and coupling between processes cannot be captured by relatively coarse spatial resolution (> 50 km) global CCMs (Markakis et al., 2014) and necessitate subsequent downscaling modelling exercises.

The skill of CCMs is typically assessed by their ability to reproduce observed abundance, and trends and variability of chemical compounds. However, uncertainty remains large because of observation limitations (errors and uncertainties, spatial and temporal coverage), model parameterizations (e.g., chemical mechanisms, photolysis schemes, parameterizations for mixing and convective transport, and deposition), model input parameters (e.g., reaction rate constants, emissions) and an incomplete understanding of the physical and chemical processes that determine SLCF distributions (Brasseur and Jacob, 2017; Young et al., 2018). CCMs can therefore not capture every aspect of atmospheric chemical composition, but are expected to represent, as faithfully as possible, the sensitivity of chemical compounds to their drivers (e.g., anthropogenic emissions). Models are evaluated in multiple ways to identify their strengths and weaknesses in explaining the evolution of SLCF abundances. For example, CCM simulations are performed in the nudged or offline meteorology mode, that is, driven by observed or reanalysed meteorology rather than in the free-running mode, for consistent comparison of modelled chemical composition with observations for a specific time period (Dameris and Jöckel, 2013). Although, caution is exercised as nudging can alter the model climate resulting in unintentional impacts on the simulated atmospheric physics and/or chemistry (Orbe et al., 2018; Chrysanthou et al., 2019). Chemical mechanisms implemented in CCMs are evaluated and intercompared to assess their skill in capturing relevant chemistry features (e.g., Brown-Steiner et al. 2018). The multi-model ensemble approach, employed for evaluating climate models, has been particularly useful for characterizing errors in CCM simulations of SLCFs related to structural uncertainty and internal variability (Naik et al., 2013b; Shindell et al., 2013; Turnock et al., 2020; Young et al., 2013). However, as discussed in BOX 4.1, this approach is unable to capture the full uncertainty range.

This assessment draws upon results from single model studies and recent multi-model intercomparisons (e.g., AeroCom, CCMI), in particular those endorsed by CMIP6, which then allows for the full consideration of robustness and uncertainty due to model structures and processes. Based on the collective information provided in this body of literature, the CMIP6 multimodel ensemble is largely fit-for-purpose of evaluating the influence of SLCFs on radiative forcing, climate and non-CO_2 biogeochemical feedbacks. Additionally, CMIP6 models are fit for capturing global air pollution response to changes in emissions and meteorology but have difficulty in simulating the mean state (Turnock et al., 2020). The set of CMIP6 simulations has been used to update the relations between emissions and surface temperature at the heart of the emulators (Cross-Chapter box 7.1) and update emission metrics (Section 7.6). Emulators and emission metrics are used in this chapter (Sections 6.5 and 6.7) to assess more specifically the effect of the individual SLCFs for each sector and region which would be of prohibitive computing cost with CCMs. CCMs are also used to build global source-receptor models which use relations between surface concentrations and emissions. Such a model is used to assess the impact of various mitigation on air quality (Sections 6.5 and 6.7.)

[END BOX 6.1 HERE]

6.3.1 Methane (CH_4)

The global mean surface mixing ratio of methane has increased by 156% since 1750 (see Section 2.2.3.4; Annex III). Since AR5, the methane mixing ratio has increased by about 3.5% from 1803±2 ppb in 2011 to 1866±3 ppb in 2019 (see Section 2.2.3.3.2) largely driven by anthropogenic activities as assessed in Chapter 5 (Section 5.2.2 and Cross-Chapter Box 5.2).

An assessment of the global methane budget is provided in Chapter 5, while this section assesses methane atmospheric lifetime and perturbation time (Prather et al., 2001). AR5 based its assessment of methane lifetime on (Prather et al., 2012). The methane lifetime due to tropospheric OH, the primary sink of methane, was assessed to be 11.2 ± 1.3 years constrained by surface observations of methyl chloroform (MCF), and lifetimes due to stratospheric loss[2], tropospheric halogen loss and soil uptake were assessed to be 150 ± 50 years, 200 ± 100 years, 120 ± 24 years, respectively (Myhre et al., 2013b). Considering the full range of individual lifetimes, the total methane lifetime was assessed in AR5 to be 9.25 ± 0.6 years.

The global chemical methane sink, essentially due to tropospheric OH, required to calculate the chemical lifetime is estimated by either bottom-up global CCMs and ESMs (BU) or top-down observational inversion methods (TD). BU global models represent the coupled chemical processes and feedbacks that determine the chemical sinks but show large diversity in their estimates, particularly the tropospheric OH sink (Zhao et al., 2019b; Stevenson et al., 2020). TD inversion methods, on the contrary, provide independent observational constraints on methane sink due to tropospheric OH over large spatio-temporal scales, but are prone to observational uncertainties and do not account for the chemical feedbacks on OH (Prather and Holmes, 2017; Naus et al., 2019). The central estimate of mean chemical methane loss over the period 2008-2017 varies from 602 [minimum and maximum range of 507-803] Tg yr^{-1} from BU chemistry-climate models in the Chemistry Climate Modeling Initiative (CCMI) to 514 [474-529] Tg yr^{-1} from TD inverse modelling (also see section 5.2.2 and Table 5.2). The smaller range in TD estimate (11%) results from the use of a common climatological mean OH distribution (Saunois et al., 2020; Zhao et al., 2020a) while the larger range in BU estimate (49%) reflects the diversity in OH concentrations from different chemical mechanisms implemented in the global models (Zhao et al., 2019b). See Section 6.3.3 for further discussion on the conflicting information on OH from CCMs/ESMs and TD inversion approaches. Further work is required to reconcile differences between BU and TD estimates of the chemical methane sink.

[START TABLE 6.2HERE]

Table 6.2: Methane lifetime due to chemical losses, soil uptake, and total atmospheric lifetime based on CMIP6 multi-model analysis, and bottom-up and top-down methane budget estimates in Table 5.2. Bottom-up and top-down methane lifetimes are calculated using the central estimates of the respective sinks for the mean 2008-2017 period in Table 5.2 together with mean 2008-2017 global methane concentration of 1815 ppb (see Annex III) converted to methane burden using a fill-factor of 2.75 Tg/ppb from Prather et al., (2012). Values in parentheses show the minimum and maximum range.

[2] Prather et al (2012) report lifetime due to stratospheric loss and soil uptake as 120 ± 24 years and 150 ± 50 years, respectively, and they were inadvertently swapped in AR5 with no effect on the total methane lifetime.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Study	Total Chemical Lifetime (yr)	Soil Lifetime (yr)	Total Atmospheric Lifetime (yr)	Number of models/inversions

[c] uncertainties indicate ± 1-standard deviation

[END TABLE 6.2HERE]

The present-day BU methane chemical lifetime shows a larger spread than that in the TD estimates (Table 6.2) in line with the spread seen in the sink estimates. The spread in the methane lifetime calculated by three CMIP6 ESMs is narrower and is enclosed within the spread of the BU CCMI model ensemble. Based on the consideration that the small imbalance in total methane sources versus sinks derived from TD estimates is close to the observed atmospheric methane growth rate (see Table 5.2), the TD values are assessed to be the best estimates for this assessment. The relative uncertainty (1-sigma) is taken to be the same as that in AR5, i.e., 11.8%, 33% and 10% for chemical, soil and total lifetime, respectively. The central estimate of the total atmospheric methane lifetime assessed here is the same as that in the AR5.

The methane perturbation lifetime (τ_{pert}) is defined as the e-folding time it takes for methane burden to decay back to its initial value after being perturbed by a change in methane emissions. Perturbation lifetime is longer than the total atmospheric lifetime of methane as an increase in methane emissions decreases tropospheric OH which in turn decreases the lifetime and therefore the methane burden (Prather, 1994; Fuglestvedt et al., 1996; Holmes et al., 2013; Holmes, 2018). Since perturbation lifetime relates changes in emissions to changes in burden, it is used to determine the emissions metrics assessed in Chapter 7 Section 7.6. The perturbation lifetime is related to the atmospheric lifetime as $\tau_{pert} = f * \tau_{total}$ where f is the feedback factor and is calculated as $f = 1/(1-s)$, where $s = - \delta (\ln \tau_{total})/ \delta (\ln[CH_4])$ (Prather et al., 2001). Since there are no observational constraints for either τ_{pert} or f, these quantities are derived from CCMs or ESMs. AR5 used f = 1.34 ± 0.06 based on a combination of multimodel (mostly CTMs and a few CCMs) estimates (Holmes et al., 2013). A recent model study explored new aspects of methane feedbacks finding that the strength of the feedback, typically treated as a constant, varies in space and time but will in all likelihood remain within 10% over the 21st century (Holmes, 2018). For this assessment, the value of f is assessed to be 1.30±0.07 based on a six member ensemble of AerChemMIP ESMs (Thornhill et al., 2021b). This f value is slightly smaller but within the range of the AR5 value. This results in an overall perturbation methane lifetime of 11.8 ± 1.8 years, within the range of the AR5 value of 12.4 ± 1.4 years. The methane perturbation lifetime assessed here is used in the calculation of emission metrics in Section 7.6.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

6.3.2 Ozone (O_3)

6.3.2.1 Tropospheric ozone

About ten percent of the total atmospheric ozone column resides in the troposphere. The ozone forcing on climate strongly depends on its vertical and latitudinal distribution in troposphere. The lifetime of ozone in the troposphere ranges from a few hours in polluted urban regions to up to few months in the upper troposphere. Observed tropospheric ozone concentrations range from less than 10 ppb over the tropical Pacific Ocean to as much as 100 ppb in the upper troposphere and more than 100 ppb downwind of major ozone precursor emissions regions. An ensemble of five CMIP6 models including whole atmospheric chemistry and interactive ozone has been shown to simulate consistently the present-day ozone distribution (N-S and latitudinal gradients) and its seasonal variability when compared with observations from sondes, background surface stations and satellite products (Griffiths et al., 2020). The biases, whose magnitude is similar to AR5, are lower than 15% against climatological seasonal cycle from ozonesondes with an overestimate in the Northern Hemisphere and an underestimate in the Southern Hemisphere (Griffiths et al., 2020). The CMIP6 multimodel ensemble estimate of the global mean lifetime of ozone for present day conditions is 25.5 ± 2.2 days (Griffiths et al., 2020) which is within the range of previous multi-model estimates (Stevenson et al., 2006; Young et al., 2013), indicating a *high level of confidence*.

AR5 assessed the tropospheric ozone burden to be 337±23 Tg for year 2000 based on the ACCMIP ensemble of model simulations (Myhre et al., 2013b). Multiple satellites products, ozonesondes and CCMs are used to estimate tropospheric ozone burden (Table 6.3). Satellite products provide lower-bound values as they exclude regions under polar night conditions (Gaudel et al., 2018). The tropospheric ozone burden values from multi-model exercises are within the range of the observational estimates despite different definitions of the tropopause for multi-model estimates which can lead to differences of about 10% on the ozone burden model estimates (Griffiths et al., 2020). Weighted by their number of members, CMIP6 and CCMI multimodel estimates and observational estimates of tropospheric ozone burden about year 2010, lead to an assessment of the tropospheric ozone burden of 347±28 Tg for 2010.

The tropospheric ozone budget is controlled by chemical production and loss, by STE, and by deposition at the Earth's surface, whose magnitude are calculated by CCMs (Table 6.3). Despite the high agreement of the model ensemble mean with observational estimates in present-day tropospheric ozone burden, the values of individual budget terms can vary widely across models in CMIP6 consistent with previous model intercomparison experiments (Young et al., 2018). Furthermore, single-model studies have shown that the halogen chemistry, which is typically neglected from model chemistry schemes in CCMs, may have a notable impact on the ozone budget, as halogens, particularly of marine origin, take part in efficient ozone loss catalytic cycles in the troposphere (Saiz-Lopez et al., 2012; Sarwar et al., 2015; Sherwen et al., 2016).

[END TABLE 6.3 HERE]

Because of the heterogeneous distribution of ozone, limited observations or proxies do not provide accurate information about the global preindustrial abundance, posing a challenge to the estimation of the historical evolution of tropospheric ozone. Therefore, global CCMs complemented by observations are relied upon for estimating the long-term changes in tropospheric ozone. AR5 concluded that anthropogenic changes in ozone precursor emissions are unequivocally responsible for the increase between 1850 and present (Myhre et al., 2013b). Based on limited isotopic evidence, Chapter 2 assesses that the global tropospheric ozone increased by less than 40% between 1850 and 2005 (*low confidence*) (see Section 2.2.5.3). The CMIP6 models are in line with this increase of tropospheric ozone with an ensemble mean value of 109± 25 Tg (model range) from 1850-1859 to 2005-2014 (Figure 6.4). This increase is higher than the AR5 value of 100 ± 25 Tg from 1850 to 2010 due to higher ozone precursor emissions in CMIP6. However, the AR5 and CMIP6 value are close when considering the reported uncertainties. The uncertainties are equivalent in CMIP6 and AR5 despite enhanced inclusion of coupled processes in the CMIP6 ESMs (e.g. biogenic VOC emissions or interactive stratospheric ozone chemistry).

[START FIGURE 6.4 HERE]

Figure 6.4: Time evolution of global annual mean tropospheric ozone burden (in Tg) from 1850 to 2100. Multi-model means for CMIP6 historical experiment (1850-2014) from UKESM1-LL-0, CESM2-WACCM, MRI-ESM2-0, GISS-E2.1-G and GFDL-ESM4 and for ScenarioMIP SSP3-7.0 experiment (2015-2100) are represented with their intermodel standard deviation (±1 σ , shaded areas). Observation based global tropospheric ozone burden estimate (from Table 6.3) is for 2010-2014. Tropospheric Ozone Assessment Report (TOAR) multi-model mean value (from Table 6.3) is for 2000 with a ±1 σ error-bar. Atmospheric Chemistry and Climate Model Intercomparison Project (ACCMIP) multi-model means are for 1850, 1930, 1980 and 2000 time-slices with ±1 σ error-bars. The troposphere is masked by the tropopause pressure calculated in each model using the WMO thermal tropopause definition. Further details on data sources and processing are available in the chapter data table (Table 6.SM.1).

[END FIGURE 6.4 HERE]

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Since the mid-20th century, the CMIP6 model ensemble shows a higher global trend (Figure 6.4). Since mid-1990s, the trends are better documented by observations (see also Section 2.2.5.3) and indicate spatial heterogeneity. In particular, in-situ observations at remote surface sites and in the lower free troposphere indicate positive trends that are far more common than negative trends, especially in the northern tropics and across southern and eastern Asia (Figure 6.5). The CMIP6 ensemble and observations largely agree in the magnitude of the global positive trend since 1997 (0.82±0.13 Tg yr^{-1} in the model ensemble; 0.70±0.15 Tg yr^{-1} in ozonesonde dataset; 0.83± 0.85 Tg yr^{-1} in the satellite ensemble) and qualitatively reproduce positive trends in Southern Hemisphere (Griffiths et al., 2020). More analyses are needed for evaluation in other parts of the world to assess the skill of the recent ensemble based on CMIP6 emissions.

[START FIGURE 6.5 HERE]

Figure 6.5: Decadal tropospheric ozone trends since 1994. Trends are shown at 28 remote and regionally representative surface sites (Cooper et al., 2020) and in 11 regions of the lower free troposphere (650 hPa, ca. 3.5 km) as measured by In-Service Aircraft for a Global Observing System (IAGOS) above Europe, northeastern USA, southeastern USA, western North America, northeast China, South East Asia, southern India, Persian Gulf, Malaysia/Indonesia, Gulf of Guinea and northern South America (Gaudel et al., 2020). High elevation surface sites are >1500 m above sea level. All trends end with the most recently available year but begin in 1995 or 1994. The sites and datasets are the same as those used in Figure 2.8, further details on data sources and processing are available in the Chapter 2 data table (Table 2.SM.1).

[END FIGURE 6.5 HERE]

In summary, there is *high confidence* in the estimated present-day (about 2010) global tropospheric ozone burden based on an ensemble of models and observational estimates (347±28 Tg), but there is *medium confidence* among the individual models for their estimates of the tropospheric ozone related budget terms. Evidence from successive multi-model intercomparisons and the limited isotopic evidence agree on the magnitude of the increase of the tropospheric ozone burden from 1850 to present-day in response to anthropogenic changes in ozone precursor emissions corroborating AR5 findings. This increase is assessed to be 109±25 Tg (*medium confidence*). CMIP6 model ensemble shows a constant global increase since the mid-20th century whose rate is consistent with that derived from observations since the mid-1990s.

6.3.2.2 Stratospheric ozone

Ninety percent of total-column ozone resides in the stratosphere. The chemical lifetime of ozone in the stratosphere ranges from less than a day in the upper stratosphere to several months in the lower stratosphere (Bekki and Lefevre, 2009). Global stratospheric ozone trends based on observations are assessed in Chapter 2 (Section 2.2.5.2). CMIP6 model ensemble shows that global total ozone column (TCO) has slightly changed from 1850 to 1960 (Keeble et al., 2021). The rapid decline in the 1970s and 1980s due to halogenated ODSs (as assessed in Chapter 2 Section 2.2.5.2 from observations) until the end of the 1990s followed by a slight increase since then is captured by the models (Keeble et al., 2021). Overall the observed climatology patterns and annual cycle amplitudes, are well represented in the CMIP6 ensemble mean. CMIP6 ensemble overestimates the observed TCO values by up to 6% (10-20 DU) globally in the NH and SH mid-latitudes, and in the tropics, but the trend in these regions is well captured between 1960 and 2014. However, there is poor agreement between the individual CMIP6 models in the pre-industrial and throughout the historical period, with model TCO values spread across a range of ~60 DU. The global stratospheric ozone column decreased by 14.3±8.7 DU from 1850 to 2014 (Keeble et al., 2021).

Model simulations attribute about half of the observed upper stratospheric ozone increase after 2000 to the decline of ODS since the late 1990s while the other half of the ozone increase is attributed to the slowing of gas-phase ozone destruction cycles due to cooling of the upper stratosphere by increasing GHGs (Aschmann et al., 2014; Oberländer-Hayn et al., 2015).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

In summary, global stratospheric ozone column has decreased from pre-industrial to present-day in response to the ODS-induced ozone rapid decline in the 1970s and 1980s followed by slow, and still incomplete, recovery. There is *medium confidence* that global stratospheric ozone column has changed by 14.3±8.7 DU between 1850 and 2014.

6.3.3 Precursor Gases

6.3.3.1 Nitrogen Oxides (NO_x)

The distribution of tropospheric NO_x is highly variable in space and time owing to its short lifetime coupled with highly heterogeneous emission and sink patterns. NO_x undergoes chemical processing, including the formation of nitric acid (HNO_3), nitrate (NO_3^-), organic nitrates (e.g, alkyl nitrate, peroxyacyl nitrate), and atmospheric transport, and deposition. Despite challenges in retrieving quantitative information from satellite observations (Duncan et al., 2014; Lin et al., 2015; Lorente et al., 2017; Silvern et al., 2018), improved accuracy and resolution of satellite-derived tropospheric NO_2 columns over the past two decades have advanced understanding of the global distribution, long-term trends, and source attribution of NO_x. Long-term average tropospheric NO_2 column based on multiple satellites born instruments (Figure 6.6a) reveals highest NO_2 levels over the most populated, urbanized, and industrialised regions of the world corresponding to high NO_x emission source regions (Krotkov et al., 2016; Georgoulias et al., 2019). Enhanced but highly variable NO_2 columns are also associated with biomass burning regions as well as areas influenced by lightning activity (Miyazaki et al., 2014; Tanimoto et al., 2015).

Observational constraints derived from isotopic composition of atmospheric nitrate inferred from ice cores provide evidence of increasing anthropogenic NO_x sources since pre-industrial times (Hastings et al., 2009; Geng et al., 2014). Global NO_x emission trends in bottom-up inventories (Section 6.2.1) as well as model simulations of nitrogen deposition (Lamarque et al., 2013b) are in qualitative agreement with these observational constraints. CMIP6 ESMs exhibit stable NO_x burden until early 1900s and then a sharp increase driven by a factor of three increase in emissions, however the magnitude of this increase remains uncertain due to poor observational constraints on pre-industrial concentrations of NO_x (Griffiths et al., 2020).

AR5 reported NO_2 decreases by 30-50% in Europe and North America and increases by more than a factor of two in Asia over the 1996 to 2011 based on satellite observations (Hartmann et al., 2013). Extension of this analysis covering time period up to 2015 reveals that NO_2 has continued to decline over the USA, western Europe, and Japan (Schneider et al., 2015; Duncan et al., 2016; Krotkov et al., 2016) because of effective fossil fuel NO_x emission controls (Section 6.2), although this rate of decline has slowed down post-2011 (Jiang et al., 2018b). Satellite observations also reveal a 32% decline in NO_2 column over China after peaking in 2011 (see Figure 6.6b) consistent with declining NO_x emissions (Section 6.2) due to the implementation of emission control strategies (de Foy et al., 2016; Irie et al., 2016; Liu et al., 2016a). Over South Asia, tropospheric NO_2 levels have grown rapidly with increases of 50% during 2005 to 2015 largely driven by hotspot areas in India experiencing rapid expansion of the power sector (Duncan et al., 2016; Krotkov et al., 2016). Further analysis indicates that many parts of India have also undergone a reversal in NO_2 trends since 2011 that has been attributed to a combination of factors, including a slowdown in economic growth, implementation of cleaner technologies, non-linear NO_x chemistry, and meteorological variability (Georgoulias et al., 2019). Satellite data reveals spatially heterogeneous NO_2 trends over the Middle East with an overall increase over 2005-2010 and a decrease over large parts of the region after 2011-2012. The reasons for trend reversal within individual areas are diverse, including warfare, imposed sanctions, and air quality controls (Lelieveld et al., 2015a; Georgoulias et al., 2019). Satellite-derived tropospheric NO_2 levels over Africa and Latin America do not show a clear trend; both increasing and decreasing trends are observed over large agglomerations in these regions since the early 2000s (Schneider et al., 2015; Duncan et al., 2016).

In summary, global tropospheric NO_x abundance has increased from 1850 to 2015 (*high confidence*). Satellite observations of tropospheric NO_x indicate strong regional variations in trends over 2005-2015.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

There is *high confidence* that NO_2 has declined over the USA and western Europe since the mid 1990s and increased over China until 2011. NO_2 trends have reversed (declining) over China beginning in 2012 and NO_2 has increased over South Asia by 50% since 2005 (*medium confidence*).

[START FIGURE 6.6 HERE]

Figure 6.6: Long term climatological mean (a) and time evolution (b) of tropospheric nitrogen dioxide (NO_2) vertical column density. Values come from the merged GOME/SCIAMACHY/GOME-2 (TM4NO2A version 2.3) dataset for the period 1996-2016 (Georgoulias et al., 2019). Time evolution of NO_2 column shown in panel (b) is normalized to the fitted 1996 levels for the 10 regions shown as boxes in panel (a). Further details on data sources and processing are available in the chapter data table (Table 6.SM.1).

[END FIGURE 6.6 HERE]

6.3.3.2 Carbon Monoxide (CO)

About half of the atmospheric CO burden is due to its direct emissions and the remainder is due to atmospheric oxidation of methane and NMVOCs. Reaction with OH is the primary sink of CO with a smaller contribution from dry deposition.

Since AR5, advances in satellite retrievals (e.g. Worden et al., 2013; Warner et al., 2014; Buchholz et al., 2021a), ground based column observations (e.g. Zeng et al., 2012; Té et al., 2016), airborne platforms (e.g. Cohen et al., 2018; Petetin et al., 2018), surface measurement networks (e.g., Andrews et al., 2014; Petron et al., 2019; Prinn et al., 2018; Schultz et al., 2015) and assimilation products (e.g., Deeter et al., 2017; Flemming et al., 2017; Zheng et al., 2019) have resulted in better characterization of the present day atmospheric CO distribution. Typical annual mean surface CO concentrations range from ~120 ppb in the Northern Hemisphere to ~40 ppb in the Southern Hemisphere (Petron et al., 2019). The sub-regional patterns in CO reflect the distribution of emission sources. Seasonal hotspots are linked to areas of biomass burning in tropical South America, equatorial Africa, Southeast Asia, and Australia. A study using data assimilation techniques estimates a global mean CO burden of 356 ± 27 Tg over the 2002-2013 period (Gaubert et al., 2017).

Global models generally capture the global spatial distribution of the observed CO concentrations but have regional biases of up to 50% (e.g., Emmons et al., 2020; Horowitz et al., 2020). Despite updated emissions datasets, the global multi-model and single model simulations persistently underestimate observed CO concentrations at northern high- and mid-latitudes as well as in the Southern Hemisphere but with smaller biases compared with that in the Northern Hemisphere (Monks et al., 2015b; Naik et al., 2013b; Stein et al., 2014; Strode et al., 2015). Models are biased high in the tropics, particularly over highly polluted areas in India and Eastern Asia (Strode et al., 2016; Yarragunta et al., 2017).

Estimates of global CO burden simulated by global models generally fall within the range of that derived from data assimilation techniques, though the spread across the models is large (Myriokefalitakis et al., 2016; Naik et al., 2013b; Stein et al., 2014; Zeng et al., 2015). There is a large diversity in model simulated CO budget driven by uncertainties in CO sources and sinks, particularly those related to in situ production from NMVOCs and loss due to reaction with OH (Stein et al., 2014; Zeng et al., 2015; Myriokefalitakis et al., 2016). Global CO budget analysis from a multimodel ensemble for more recent years including results from the CMIP6 model runs are not yet available.

Reconstructions of CO concentrations based on limited ice core samples in the Northern Hemisphere high latitudes suggest CO mole fractions of about 145 ppb in the 1950s, which rose by 10-15 ppb in the mid-1970s, and then declined by about 30 ppb to about 130 ppb by 2008 (Petrenko et al., 2013). The negative trends since the 1990s are often attributed to emission regulations from road transportation in North America and Europe. Due to limited observations prior to the satellite era, our knowledge on long-term global CO

ACCEPTED VERSION SUBJECT TO FINAL EDITING

trends are estimated using models. An increase of global CO burden of about 50% for the year 2000 relative to 1850 is found in CMIP6 (Griffiths et al., 2020).

AR5 reported a global CO decline of about 1% yr^{-1} based on satellite data from 2002-2010, but biases in instruments rendered low confidence in this trend. AR5 also indicated a small CO decrease from in situ networks but did not provide quantitative estimates. New analysis of CO trends performed since AR5 and based on different observational platforms and assimilation products show a decline globally and over most regions during the last one to two decades with varying amplitudes partly depending on the period of analysis (Table 6.4). Inversion based analysis attribute the global CO decline during the past two decades to decreases in anthropogenic and biomass burning CO emissions despite probable increase in atmospheric CO chemical production (Gaubert et al., 2017; Jiang et al., 2017; Zheng et al., 2019). Furthermore, (Buchholz et al., 2021) report a slowdown in global CO decline in 2010-2018 compared to 2002-2010, although the magnitude and sign of this change in the trend varies regionally. Global models prescribed with emissions inventories developed prior to the CMIP6 inventory capture the declining observed CO trends over North America and Europe but not over East Asia (Strode et al., 2016). CMIP6 models driven by CMIP6 emissions simulate a negative trend in global CO burden over the 1990-2020 period (Griffiths et al., 2020), however the simulated trends have not yet been evaluated against observations.

In summary, our understanding of present day global CO distribution has increased since AR5 with newer and improved observations and reanalysis. There is *high confidence* that global CO burden is declining since 2000. Evidence from observational CO reanalysis suggests this decline to be driven by reductions in anthropogenic CO emissions, however this is yet to be corroborated by global ESM studies with the most recent emission inventories.

6.3.3.3 Non-Methane Volatile Organic Compounds (NMVOCs)

NMVOCs encompass thousands of compounds with lifetimes from hours to days to months and abundances and chemical composition highly variable with respect to space, time. Although the biogenic source (Section 6.2.2) dominates the global NMVOC budget, anthropogenic activities are the main driver of long-term trends in the abundance of many compounds.

Information on the global distribution of individual NMVOCs is scarce, except for the less reactive

ACCEPTED VERSION SUBJECT TO FINAL EDITING

compounds having lifetimes of several days to months. Based on measurements from polar firn air samples and ground-based networks, AR5 reported that the abundances of the predominantly anthropogenic light alkanes (C_2-C_5) increased until 1980 and declined afterwards. The decline was attributed to air quality emission controls and to fugitive emission decreases following the collapse of the Soviet Union (Simpson et al., 2012). Since AR5, scarce ground-based measurements have shown that the decline in C_2-C_3 alkanes ended around 2008 and their abundances are since growing again, which is primarily attributed to increasing North American emissions (see Section 6.2.1). Furthermore, since AR5 the evolution of ethane levels during the past millennium was made accessible by analysis of ice core samples (Nicewonger et al., 2016). The large observed interpolar ratio of ethane in preindustrial times (3.9) corroborates a large geologic source of ethane previously put forward by (Etiope and Ciccioli, 2009), and narrows down its likely global magnitude (Nicewonger et al., 2018) (*low to medium confidence*). The incorporation of geologic emissions in CCMs is not yet systematic though a one-model study has shown improved agreement of the results with observations (Dalsøren et al., 2018).

Formaldehyde is a short-lived high-yield product of NMVOC oxidation and formaldehyde column data from satellite instruments can therefore inform on trends in anthropogenic NMVOC abundances over very industrialized region. AR5 reported significant positive trends in HCHO between 1997 and 2009 over north-eastern China (4% yr^{-1}) and negative trends over north-eastern U.S. cities. Since AR5, there is *robust evidence* and *high agreement* of an upward trend of HCHO over eastern China, though large regional disparities exist in the trends (De Smedt et al., 2015; Shen et al., 2019) with possible negligible or decreasing trend over Beijing and the Pearl River Delta. In other world regions, in particular North America, there is *limited to medium evidence* for significant changes in the HCHO columns, except in regions where the trend is particularly strong, e.g. the Houston area (-2.2% yr^{-1} over 2005-2014) and the Alberta oil sands (+3.8% yr^{-1}) (Zhu et al., 2017). Over the north-eastern U.S., even the sign of the trend differs between studies (De Smedt et al., 2015; Zhu et al., 2017) for reasons that are unclear.

In summary, after a decline between 1980 and 2008, abundances of light NMVOCs have increased again over the Northern Hemisphere due to extraction of oil and gas in North America (*high confidence*). Trends in satellite HCHO observations, used as a proxy of anthropogenic NMVOC over industrialised areas, show a significant positive trend over Eastern China (*high confidence*) but also indicate large regional disparities in the magnitude of the trends over China and even in their signs over North America.

6.3.3.4 Ammonia (NH_3)

Ammonia is the most abundant alkaline gas in the atmosphere. Its present-day source is dominated by livestock and crop production (section 6.2). Ammonia reacts with nitric acid and sulphuric acid to produce ammonium sulphate and ammonium nitrate, which contribute to the aerosol burden (see section 6.3.5.2), promotes aerosol nucleation by stabilizing sulphuric acid clusters (Kirkby et al., 2011) and contributes to nitrogen deposition (see section 6.4.4) (Sheppard et al., 2011; Flechard et al., 2020). Trends in NH_3 were not assessed in AR5.

Considerable expansion of satellite (Clarisse et al., 2009; Shephard and Cady-Pereira, 2015; Warner et al., 2016) and ground-based observations (Miller et al., 2014; Li et al., 2016; Pan et al., 2018) has improved our understanding of the spatial distribution and seasonal to inter-annual variability of ammonia, and advanced its representations in models (e.g., Zhu et al., 2015). Regionally, peak NH_3 concentrations are observed over large agricultural (e.g., Northern India, US Midwest and Central Valley) and biomass burning regions, in good qualitative agreement with emission inventories (Van Damme et al., 2015, Van Damme et al., 2018). However, several large agricultural and industrial hotspots have been found to be missing or greatly underestimated in emission inventories (Van Damme et al., 2018). NH_3 exhibits a strong vertical gradient, with a maximum in the boundary layer (Schiferl et al., 2016) and can be transported into the upper troposphere and lower stratosphere (UTLS), particularly in the Asian Monsoon region, as indicated by observations (Froyd et al., 2009; Höpfner et al., 2016, 2019) and theoretical considerations (Ge et al., 2018). There is a large range in the present-day NH_3 burden (from 0.04 to 0.7 TgN) simulated by CCMs, highlighting deficiencies in the process-level representation of NH_3 in current global models (Bian et al.,

ACCEPTED VERSION SUBJECT TO FINAL EDITING

2017). The underestimate of surface NH_3 concentrations (Bian et al., 2017) further highlights such deficiencies and the limitations in comparing site-specific observations with relatively coarse-resolution models.

Observations show that NH_3 concentration has been increasing in recent decades in the USA (Butler et al., 2016; Warner et al., 2016; Yu et al., 2018), western Europe (van Zanten et al., 2017; Warner et al., 2017, Wichink Kruit et al., 2017; Tang et al., 2018b), and China (Warner et al., 2017; Liu et al., 2018). This trend has been attributed to a combination of increasing ammonia emissions (Sutton et al., 2013; Fowler et al., 2015) and decreases in the chemical reaction of NH_3 with nitric and sulphuric acids associated with reductions in SO_2 and NO_x emissions whose rate depends on the region (Warner et al., 2017; Yao and Zhang, 2019). Over longer time scales, CCMs simulate an increase of the NH_3 burden by a factor of 2 to 7 since preindustrial conditions (Xu and Penner, 2012; Hauglustaine et al., 2014).

In summary, progress has been made in the understanding of the spatio-temporal distribution of ammonia, though representation of NH_3 remains rather unsatisfactory due to process-level uncertainties. Evidence from observations and models suggests that ammonia concentrations have been increasing over the recent decades due to emissions and chemistry. There is *high confidence* that the global NH_3 burden has increased considerably from preindustrial to present-day although the magnitude of the increase remains uncertain.

6.3.3.5 Sulphur Dioxide (SO_2)

AR5 did not assess trends in SO_2 concentrations. Trends in SO_2 abundances are consistent with the overall anthropogenic emission changes as presented in Section 6.2 and Figure 6.18. Long-term surface-based in situ observations in North America and Europe show reductions of more than 80% since the measurements began around 1980 (Table 6.5). Europe had the largest reductions in the first part of the period while the highest reduction came later in North America. Observed trends are qualitatively reproduced by global and regional models over North America and Europe over the period 1990-2015 for which emission changes are well quantified (Table 6.5) (Aas et al., 2019).

In situ observations over other parts of the world are scattered. However, the limited in-situ observations in East Asia indicate an increase in atmospheric SO_2 up to around 2005 and then a decline (Aas et al., 2019). This is confirmed by satellite observations (Krotkov et al., 2016), which further reveal a rapid decline in SO_2 since 2012 to 2013 (Krotkov et al., 2016; Zheng et al., 2018b). In India, on the other hand, the SO_2 levels have doubled over 2005 to 2015 (Krotkov et al., 2016).

In summary, surface and satellite observations indicate strong regional variations in trends of atmospheric SO_2 abundance. The SO_2 concentrations in North America and Europe have declined over 1980 to 2015 with slightly stronger reductions in North America (70 ± 20%) than over Europe (58 ± 32%) over 2000-2015, though Europe had larger reductions than the US in the prior decade (1990-2000). In Asia, the SO_2 trends are more scattered, though there is *medium confidence* that there was a strong increase up to around 2005, followed by a steep decline in China, while over India, the concentrations are increasing steadily.

6.3.4 Short-lived Halogenated Species

The halogenated species are emitted in the atmosphere in the form of the synthetically produced chlorofluorocarbons (CFCs), halons, hydrochlorofluorocarbons (HCFCs), hydrofluorocarbons (HFCs) and others. Their historical global abundances are provided in Annex III and discussed in Chapter 2 (Section 2.2.4, Table 2.3). In summary, for the period 2011-2019, the abundance of total chlorine from HCFCs has continued to increase in the atmosphere with decreased growth rates, total tropospheric bromine from halons and methyl bromide continued to decrease while abundances of most currently measured HFCs increased significantly, consistent with expectations based on the ongoing transition away from the use of ODSs. Here, emphasis is given on the very short-lived halogenated species (VSLSs). The trends for these species were not discussed in IPCC AR5.

VSLSs are halogenated substances with atmospheric lifetimes less than 0.5 year. While longer-lived ODSs account for most of the present day stratospheric halogen loading, there is *robust evidence* that VSLSs contribute to stratospheric bromine and chlorine (Carpenter et al., 2014; Hossaini et al., 2015; Leedham Elvidge et al., 2015b) thus also contributing to stratospheric ozone depletion.

Of the atmospheric VSLSs, brominated and iodinated species are predominantly of oceanic origin, while chlorinated species have significant additional anthropogenic sources (Carpenter et al., 2014; Hossaini et al., 2015). Global mean chlorine from the VSLSs has increased in the troposphere from about 91 ppt in 2012 to about 110 ppt in 2016 (Engel et al., 2018). This increase is mostly due to dichloromethane (CH_2Cl_2), a species that has predominantly anthropogenic sources reflected by 3-times higher concentrations in the Northern Hemisphere than in the Southern Hemisphere (Hossaini et al., 2017). The upward dichloromethane

ACCEPTED VERSION SUBJECT TO FINAL EDITING

trend is corroborated by upper tropospheric aircraft data over the period 1998-2014 (Leedham Elvidge et al., 2015a; Oram et al., 2017). The observations from the surface networks show that the abundance of dichloromethane continued to increase until 2019 (Annex III), although the accuracy of global abundance of VSLSs is limited by the limited coverage by networks. No long-term change of the bromine containing VSLSs have been observed (Engel et al., 2018).

6.3.5 Aerosols

This section assesses trends in atmospheric distribution of aerosols and improvements in relevant physical and chemical processes. The observed large-scale temporal evolution of aerosols is assessed in Section 2.2.6. Since AR5, long term measurements of aerosol mass concentrations from regional global surface networks have continued to expand and provide information on the distribution and trends in aerosols (Figure 6.7). There is large spatial variability in aerosol mass concentration, expressed as $PM_{2.5}$, dominant aerosol type and aerosol composition, consistent with the findings in AR5.

[START FIGURE 6.7 HERE]

Figure 6.7: Distribution of $PM_{2.5}$ composition mass concentration (in µg m^{-3}) for the major $PM_{2.5}$ aerosol components. Those aerosol components are sulphate, nitrate, ammonium, sodium, chloride, organic carbon, and elemental carbon. The central world map depicts the intermediate level regional breakdown of observations (10 regions) following the IPCC Sixth Assessment Report Working Group III (AR6 WGIII). Monthly averaged $PM_{2.5}$ aerosol component measurements are from: (i) the Environmental Protection Agency (EPA) network which include 211 monitor sites primarily in urban areas of North America during 2000-2018 (Solomon et al., 2014) (ii) the Interagency Monitoring of Protected Visual Environments (IMPROVE) network during 2000-2018 over 198 monitoring sites representative of the regional haze conditions over North America, (iii) the European Monitoring and Evaluation Programme (EMEP) network over 70 monitoring in Europe and (eastern) Eurasia during 2000-2018, (iv) the Acid Deposition Monitoring Network in East Asia (EANET) network with 39 (18 remote, 10 rural, 11 urban) sites in Eurasia, Eastern Asia, South-East Asia and Developing Pacific, and Asia-Pacific Developed during 2001-2017, (v) the global Surface Particulate Matter Network (SPARTAN) during 2013-2019 with sites primarily in highly populated regions around the world (i.e, North America, Latin America and Caribbean, Africa, Middle East, Southern Asia, Eastern Asia, South-Eastern Asia and Developing Pacific) (Snider et al., 2015, 2016), and (vii) individual observational field campaign averages over Latin America and Caribbean, Africa, Europe, Eastern Asia, and Asia-Pacific Developed (Celis et al., 2004; Feng et al., 2006; Mariani and de Mello, 2007; Molina et al., 2007, 2010; Bourotte et al., 2007; Fuzzi et al., 2007; Mkoma, 2008; Favez et al., 2008; Aggarwal and Kawamura, 2009; Mkoma et al., 2009; Li et al., 2010; Martin et al., 2010; Radhi et al., 2010; Weinstein et al., 2010; de Souza et al., 2010; Batmunkh et al., 2011; Pathak et al., 2011; Gioda et al., 2011; Zhang et al., 2012a; Zhao et al., 2013; Cho and Park, 2013; Wang et al., 2019; Kuzu et al., 2020). Further details on data sources and processing are available in the chapter data table (Table 6.SM.1).

[END FIGURE 6.7 HERE]

Remote sensing instruments provide a larger-scale view of aerosol distributions and trends than ground-based monitoring networks by retrieving the Aerosol optical depth (AOD), which is indirectly related to aerosol mass concentrations. AOD is the column-integrated aerosol mass extinction at a given wavelength, and is therefore relevant to the estimation of the radiative forcing of aerosol-radiation interactions (Section 7.3.3.1). Models participating in Phase III of the AeroCom intercomparison project were found to underestimate present-day AOD by about 20% (Gliß et al., 2020), although different remote sensing estimates obtain different estimates of global mean AOD. Gliß et al. (2020) also highlight the considerable diversity in the simulated contribution of various aerosol types to total AOD. However, models simulate regional trends in AODs that agree well, when expressed as percentage change, with ground- (Gliß et al., 2020; Mortier et al., 2020) and satellite-based (Cherian and Quaas, 2020a; Gliß et al., 2020) observations. AOD trends simulated by CMIP6 models are more consistent with satellite-derived trends than CMIP5

ACCEPTED VERSION SUBJECT TO FINAL EDITING

models for several subregions, thanks to improved emission estimates (Cherian and Quaas, 2020b).

All CMIP6 models simulate a positive trend in global mean AOD since 1850, with a strong increase after the 1950s coinciding with the massive increase in anthropogenic SO_2 emissions (Figure 6.8). Global mean AOD increases have slowed since 1980, or even reversed in some models, as a result of a compensation between SO_2 emission decreases over the United States and Europe in response to air quality controls since the mid-1980s and increases over Asia. Since the mid-2000s, global mean AOD stabilized driven by soaring emissions in South Asia, and declining emissions in East Asia (section 6.2.1). Trends post ~2010 are difficult to assess from CMIP6 models since the historical simulations end at 2014. Nevertheless, the strong decline in anthropogenic SO_2 emissions over East Asia since 2011 is underestimated in the CMIP6 emission database (Hoesly et al., 2018) indicating that the observed AOD change over East Asia may not be captured accurately by CMIP6 models (Wang et al., 2021). While all CMIP6 models simulate increase of AOD between 1850 and 2014 there is strong inter-model diversity in the simulated AOD change since 1850 ranging from 0.01 (15%) to 0.08 (53%) in 2014. Some models therefore lie outside the 68% confidence interval of 0.02 (15%) to 0.04 (or 30%) for global AOD change in 2005-2015 compared to 1850 estimated by (Bellouin et al., 2020) based on observational and model (excluding CMIP6) lines of evidence. In addition to the horizontal distribution of aerosols documented by AOD, their number size distribution, vertical distribution, optical properties, hygroscopicity, ability to act as CCN, chemical composition, mixing state and morphology are key elements to assess their climate effect (see Section 6.4.).

[START FIGURE 6.8 HERE]

Figure 6.8: Time evolution of changes in global mean aerosol optical depth (AOD) at 550 nm. Year of reference is 1850. Data shown from individual Coupled Model Intercomparison Project Phase 6 (CMIP6) historical simulations. Each time series corresponds to the ensemble mean of realizations done by each model. Simulation results from years including major volcanic eruptions, e.g. Novarupta (1912) and Pinatubo (1991), are excluded from the analysis for models encompassing the contribution of stratospheric volcanic aerosols to total AOD. Further details on data sources and processing are available in the chapter data table (Table 6.SM.1).

[END FIGURE 6.8 HERE]

6.3.5.1 Sulphate (SO_4^{2-})

Sulphate aerosols (or sulphate containing aerosols) are emitted directly or formed in the atmosphere by gas and aqueous phase oxidation of precursor sulphur gases, including SO_2, DMS, and carbonyl sulphide (OCS), emitted from anthropogenic and natural sources (Section 6.2). Sulphate aerosols influence climate forcing directly by either scattering solar radiation or absorbing longwave radiation, and indirectly by influencing cloud micro- and macrophysical properties and precipitation (Boucher et al., 2013; Myhre et al., 2013b). Additionally, sulphate aerosols and sulphate deposition have a large impact on air quality and ecosystems (Reis et al., 2012). The majority of sulphate particles are formed in the troposphere, however, SO_2 and other longer-lived natural precursors, such as OCS, transported into the stratosphere contribute to the background stratospheric aerosol layer (Kremser et al., 2016). SO_2 emissions from volcanic eruptions are a significant source of stratospheric sulphate loading (see Chapter 2 for reconstruction of stratospheric aerosol optical depth and Chapter 7 for radiative forcing of volcanic aerosols). Furthermore, studies suggest contributions from anthropogenic SO_2 emissions transported into the stratosphere with a consequent impact on radiative forcing (Myhre et al., 2004; Yu et al., 2016). However there is significant uncertainty in the relative importance of this stratospheric sulphate source (Kremser et al., 2016).

Process understanding of sulphate production pathways from SO_2 emissions has seen some progress since AR5. More specifically, many global climate models now have a more complete description of chemical reactions such that oxidant levels s (including ozone) are better described, include a pH-dependence of SO_2 oxidation (e.g., Bauer et al., 2020; Kirkevåg et al., 2018), and implement explicit descriptions of ammonium and nitrate aerosol components, which may influence the partitioning of sulphate (Bian et al., 2017; Lund et

ACCEPTED VERSION SUBJECT TO FINAL EDITING

al., 2018). The pH influences the heterogeneous chemistry as well as the physical properties of the aerosols, and this topic has been a subject of growing interest since AR5 (Cheng et al., 2016; Freedman et al., 2019; Nenes et al., 2020). Increases in cloudwater pH have been shown to significantly increase the radiative forcing of sulphates (Turnock et al., 2019).

Sulphate is removed from the atmosphere by dry deposition and wet scavenging, and these processes depend on the characteristics of the Earth's surface, and the intensity, frequency and amount of precipitation (Boucher et al., 2013). Even though there have been some improvements since AR5, model representation of wet scavenging and related cloud processes, and atmospheric transport remains a key source of uncertainty in the simulated aerosol distribution and lifetime with further consequences for the sulphate forcing estimates (Kristiansen et al., 2016; Lund et al., 2018a). There are also still relatively large uncertainties in the emission height used in models affecting the simulated aerosol distribution (Yang et al., 2019).

Based on long-term surface-based in situ observations, AR5 reported strong decline in sulphate aerosols in Europe and the USA over 1990 to 2009, with the largest decreases occurring before 2000 in Europe and post 2000 in the USA. Since AR5, atmospheric measurements in conjunction with model results have provided insights into the spatial and temporal distribution of sulphate and sulphur deposition (Vet et al., 2014; Tan et al., 2018; Aas et al., 2019). The *in situ* observations in North America and Europe reveal substantial reduction since the measurements started around 1980, though the trends have not been linear through this period (Table 6.5). Several regional studies agree with these trend estimates for Europe (Banzhaf et al., 2015b; Theobald et al., 2019) and North America (Sickles II and Shadwick, 2015; Paulot et al., 2016a). Further, the concentrations of primary emitted SO_2 (Section 6.3.3.5) show greater decreases than secondary sulphate aerosols over these regions due to a combination of higher oxidation rate (hence more SO_2 converted to SO_4^{2-}) and increased dry deposition rate of SO_2 (Fowler et al., 2009; Banzhaf et al., 2015). In situ observations over other parts of the world are scattered (see Figure 6.7), and the lack of observations makes it too uncertain to quantify regional representative trends (Hammer et al., 2018). However, limited in-situ observations in East Asia indicate an increase in atmospheric sulphate up to around 2005 and then a decline (Aas et al., 2019) which is confirmed by satellite observations of SO_2 (Section 6.3.3.5). In India, on the other hand satellite observations indicate a rapid increase in the SO_2 levels (Krotkov et al., 2016), and long-term measurements of sulphate in precipitation in India further provide evidence of an increasing trend from 1980 to 2010 (Bhaskar and Rao, 2017; Aas et al., 2019). Further improvements in global trend assessments are expected with new integrated reanalysis products from the Earth-system data assimilation projects (Randles et al., 2017; Inness et al., 2019).

Indirect evidence of decadal trends in the atmospheric loading of sulphur are provided by Alpine ice cores, mainly influenced by European sources (Engardt et al., 2017), and ice cores from Svalbard (Samyn et al., 2012) and Greenland (Patris et al., 2002; Iizuka et al., 2018) influenced by sources in Europe and North America. These show similar patterns with a weak increase from the end of the 19th century up to around 1950 followed by a steep increase up to around 1980, and then a significant decrease over the next two decades. This general trend is consistent with the emissions of SO_2 in North America and Europe (Hoesly et al., 2018; Figures 6.18; 6.19).

Global and regional models qualitatively reproduce observed trends over North America and Europe for the period 1990-2015 for which emission changes are generally well quantified (Aas et al., 2019; Mortier et al., 2020), building confidence in the relationship between emissions, concentration, deposition and radiative forcing derived from these models. Though, the models seem to systematically underestimate sulphate (Bian et al., 2017; Lund et al., 2018a) and AOD (Lund et al., 2018a; Gliß et al., 2020), and there are quite large differences in the models' distribution of the concentration fields of sulphate driven by differences in the representation of photochemical production and sinks of aerosols. One global model study also highlighted biases in simulated sulphate trends over the 2001-2015 period over eastern China due to uncertainties in the CEDS anthropogenic SO_2 emissions trends (Paulot et al., 2018).

In summary, there is *high confidence* that the global tropospheric sulphate burden increased from 1850 to around 2005, but there are large regional differences in the magnitude. Sulphate aerosol concentrations in North America and Europe have declined over 1980 to 2015 with slightly stronger reductions in North

ACCEPTED VERSION SUBJECT TO FINAL EDITING

America (47%) than over Europe (40%) over 2000-2015, though Europe had larger reductions in the prior decade (1990-2000), 52% and 21% respectively for Europe and North America. In Asia, the trends are more scattered, though there is *medium confidence* that there was a strong increase up to around 2005, followed by a steep decline in China, while over India, the concentrations are increasing steadily.

6.3.5.2 Ammonium (NH_4^+), and Nitrate Aerosols (NO_3^-)

Ammonium sulphate and ammonium nitrate aerosols are formed when NH_3 reacts with nitric acid (HNO_3) and sulphuric acid (H_2SO_4) produced in the atmosphere by the oxidation of NO_x and SO_2, respectively. Ammonium nitrate is formed only after H_2SO_4 is fully neutralized. NH_4^+ and NO_3^- aerosols produced via these gas-to-particle reactions are a major fraction of fine-mode particles (with diameter < 1μm) affecting air quality and climate. Coarse-mode nitrate, formed by the heterogeneous reaction of nitric acid with dust and sea salt, dominates the overall global nitrate burden, but has little radiative effect (Hauglustaine et al., 2014; Bian et al., 2017). Trends in ammonium (NH_4^+) and nitrate (NO_3^-) were not assessed in AR5.

Global model present-day estimates of the global NH_4^+ burden range from 0.1 to 0.6 TgN (Bian et al., 2017). Models generally simulate surface NH_4^+ concentrations better than surface NH_3 concentrations (Bian et al., 2017), which reflects its thermodynamic control by SO_4^{2-} rather than NH_3 (Shi et al., 2017). The concomitant increases of NH_3, SO_2, and NO_x emissions (see Section 6.2) have led to a factor of 3 to 9 increase in the simulated NH_4^+ burden from 1850 to 2000 (Hauglustaine et al., 2014; Lund et al., 2018a), driven primarily by ammonium sulphate (70-90%). The increases in the NH_3 and NH_4^+ burdens are indirectly supported by the observed increase of NH_4^+ concentration in ice cores in mid to high latitudes (Kang et al., 2002; Kekonen et al., 2005; Lamarque et al., 2013a; Iizuka et al., 2018).

Ammonium nitrate is semi-volatile, which results in complex spatial and temporal patterns in its concentrations (Putaud et al., 2010; Hand et al., 2012a; Zhang et al., 2012b) reflecting variations in its precursors, NH_3 and HNO_3, as well as SO_4^{2-}, non-volatile cations, temperature and relative humidity (Nenes et al., 2020). High relative humidity and low temperature as well as elevated fine particulate matter loading (Huang et al., 2014; Petit et al., 2015; Li et al., 2016; Sandrini et al., 2016) favour nitrate production. Measurements reveal high contribution of NO_3^- to surface $PM_{2.5}$ (>30%) in regions with elevated regional NO_x and NH_3 emissions, such as the Paris area (Beekmann et al., 2015; Zhang et al., 2019), northern Italy (Masiol et al., 2015; Ricciardelli et al., 2017), Salt Lake City (Kuprov et al., 2014; Franchin et al., 2018), the North China Plains (Guo et al., 2014; Chen et al., 2016), and New Delhi (Pant et al., 2015). Recent observations also show that ammonium nitrate contributes to the Asian tropopause aerosol layer (Vernier et al., 2018; Höpfner et al., 2019). Model diversity in simulating present-day global fine-mode NO_3^- burden is large with two multimodel intercomparison studies reporting estimates in the range of 0.14-1.88 Tg and 0.08-0.93 Tg, respectively (Bian et al., 2017; Gliß et al., 2021). Models differ in their estimates of the global tropospheric nitrate burden by up to a factor of 13 with differences remain nearly the same across CMIP5 and CMIP6 generation of models (Bian et al., 2017; Gliß et al., 2021). While regional patterns in the concentration of fine-mode NO_3^- are qualitatively captured by models, the simulation of fine-mode NO_3^- is generally worse than that of NH_4^+ or SO_4^{2-} (Bian et al., 2017). This can be partly attributed to the semi-volatile nature of ammonium nitrate and biases in the simulation of its precursors (Heald et al., 2014; Paulot et al., 2016), including the sub-grid scale heterogeneity in NO_x and NH_3 emissions (Zakoura and Pandis, 2018).

Models indicate that the burden of fine-mode NO_3^- has increased by a factor of 2-5 from 1850 to 2000 (Xu and Penner, 2012; Hauglustaine et al., 2014; Lund et al., 2018a), an increase that has accelerated between 2001 and 2015 (Lund et al., 2018a; Paulot et al., 2018). The sensitivity of NO_3^- to changes in NH_3, SO_4^{2-}, and HNO_3 is determined primarily by aerosol pH, temperature, and aerosol liquid water (Guo et al., 2016, 2018; Weber et al., 2016; Nenes et al., 2020). In regions, where aerosol pH is high, changes in NO_3^- follow changes in NO_x emissions, consistent with the observed increase of ammonium nitrate in Northern China from 2000 to 2015 (Wen et al., 2018) and its decrease in the US Central Valley (Pusede et al., 2016). In contrast, the decrease in SO_2 emissions in the US Southeast has caused little change in NO_3^- from 1998 to 2014 as nitric acid largely remains in the gas phase due to highly acidic aerosols (Weber et al., 2016; Guo et al., 2018).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

In summary, there is *high confidence* that the NH_4^+ and NO_3^- burdens have increased from preindustrial to present-day, although the magnitude of the increase is uncertain especially for NO_3^-. The sensitivity of NH_4^+ and NO_3^- to changes in NH_3, H_2SO_4, and HNO_3 is well understood theoretically. However, it remains challenging to represent in models in part because of uncertainties in the simulation of aerosol pH and only a minority of ESMs consider nitrate aerosols in CMIP6.

6.3.5.3 Carbonaceous Aerosols

Carbonaceous aerosols are black carbon (BC)[3], which is soot made almost purely of carbon, and organic aerosols[4] (OA), which also contain hydrogen and oxygen and can be of both primary (POA) or secondary (SOA) origin. BC and a fraction of OA called Brown Carbon (BrC) absorb solar radiation. The various components of carbonaceous aerosols have different optical properties, so the knowledge of their partition, mixing, coating and ageing is essential to assess their climate effect (see Section 7.3.3.1.2).

Carbonaceous aerosols receive attention in the scientific and policy arena due to their radiative forcing, and their sizeable contribution to PM in an air quality context (Rogelj et al., 2014b; Harmsen et al., 2015; Shindell et al., 2016; Haines et al., 2017a; Myhre et al., 2017). BC exerts a positive ERF, but the ERF of carbonaceous aerosol as a whole is negative (Bond et al., 2013; Thornhill et al., 2021b). On average, carbonaceous aerosols accounts for 50 to 70% of PM with diameter lower than 1 µm in polluted and pristine areas (Zhang et al., 2007; Carslaw et al., 2010; Andreae et al., 2015; Monteiro dos Santos et al., 2016; Chen et al., 2017).

An extensive review on BC (Bond et al., 2013) discussed limitations in inferring its atmospheric abundance and highlighted inconsistencies between different terminology and related measurement techniques (Petzold et al., 2013; Sharma et al., 2017). Due to a lack of global observations, AR5 only reported declining total carbonaceous aerosol trends from USA and declining BC trend from the Arctic based on data available up to 2008. Since AR5, the number of observation sites has grown worldwide (see also Figure 6.7) but datasets suitable for global trend analyses remain limited (Reddington et al., 2017; Laj et al., 2020). Locally, studies based on observations from rural and background sites have reported decreasing surface carbonaceous aerosol trends in the Arctic, Europe, USA, Japan and India (Table 6.6). Increases in carbonaceous aerosol concentrations in some rural sites of the Western USA have been associated with wildfires (Hand et al., 2013; Malm et al., 2017). Long-term OA observations are scarce, so their trends outside of the USA are difficult to assess. Ice-core analysis have provided insight into carbonaceous aerosol trends predating the satellite and observation era over the Northern Hemisphere (Section 2.2.6, Figure 2.9b).

[START TABLE 6.6 HERE]

Table 6.6: Summary of the regional carbonaceous aerosol trends at background observation sites.

Species	Analysis period	Change/Trends	References
BC	1990-2009	Arctic Sites (Alert, Barrow, Ny-Alesund)) $-2\%\ yr^{-1}$	(Sharma et al., 2013a)
	1970-2010	Finland (Kevo remote site) $-1.8\%\ yr^{-1}$	(Dutkiewicz et al., 2014)
	2005-2014	Germany (rural site) $-2\%\ yr^{-1}$	(Kutzner et al., 2018)

[3] The terms EC and BC are operationally defined on the basis of the methodology used for their quantification, i.e., thermal refractivity and light absorption, respectively, and often used interchangeably.

[4] The carbon mass fraction of OA is termed as OC, conversion factor between 1.4 to 1.6 from OC to OA are typically assumed

ACCEPTED VERSION SUBJECT TO FINAL EDITING

	2009-2016	United Kingdom (Harwell rural site) −8% yr^{-1}	(Singh et al., 2018)
	2009-2019	Japan (Fukue Island) −5.8 ± 1.5% yr^{-1}	(Kanaya et al., 2020)
	2009-2015	India (Darjeeling mountain site) −5% yr^{-1}	(Sarkar et al., 2019)
OA	2001-2015	USA (IMPROVE sites east of 100°W) −2% yr^{-1}	(Malm et al., 2017)
Total Carbon (EC+OC)	1990-2010	USA (IMPROVE sites) Western USA: −4 to −5% yr^{-1} Eastern USA: −1 to −2% yr^{-1}	(Hand et al., 2013)
	2002-2010	Spain (Montseny rural site) −5% yr^{-1}	(Querol et al., 2013)

[END TABLE 6.6 HERE]

Knowledge of carbonaceous aerosol atmospheric abundance continues to rely on global models due to a lack of global scale observations. For BC, models agree within a factor of two with measured surface mass concentrations in Europe and North America, but underestimate concentrations at the Arctic surface by one to two orders or magnitude, especially in winter and spring (Lee et al., 2013a; Lund et al., 2018a). For OA, AeroCom models underestimate surface mass concentrations by a factor 2 over urban areas, as their low horizontal resolution prevents them for resolving local pollution peaks (Tsigaridis et al., 2014; Lund et al., 2018a). Models agree within a factor of two with OA surface concentrations measured at remote sites, where surface concentrations are more spatially uniform (Tsigaridis et al., 2014).

Lifetimes in models are estimated to 5.5 days ±35% for BC and 6.0 days ±29% for OA (median ± 1 standard deviation) according to an ensemble of 14 models (Gliß et al., 2021). Disagreement in simulated lifetime leads to horizontal and vertical variations in predicted carbonaceous aerosol concentrations, with implications for radiative forcing (Lund et al., 2018b) (Samset et al., 2013). Airborne campaigns have provided valuable vertical profile measurements of carbonaceous aerosol concentrations (Schwarz et al., 2013; Freney et al., 2018; Hodgson et al., 2018; Morgan et al., 2019; Schulz et al., 2019; Zhao et al., 2019a). Compared to those measurements, models tend to transport BC too high in the atmosphere, suggesting that lifetimes are not larger than 5.5 days (Samset et al., 2013; Lund et al., 2018b). Newly developed size-dependent wet scavenging parameterisation for BC (Taylor et al., 2014; Schroder et al., 2015; Ohata et al., 2016; Zhang et al., 2017a; Ding et al., 2019; Moteki et al., 2019; Motos et al., 2019) may lead to decreased BC lifetimes and improve agreement with observed vertical profiles.

Simulated BC burdens show a large spread among models (Gliß et al., 2021), despite using harmonised primary emissions, because of differences in BC removal efficiency linked to different treatment of ageing and mixing, particularly in strong source regions. The multi-model median BC burden for the year 2010 from Gliß et al. (2021), based on 14 AeroCom models, is 0.131 ± 0.047 Tg (median ± standard deviation). That range encompasses values reported by independent single model estimates (Huang et al., 2013; Lee et al., 2013b; Sharma et al., 2013b; Wang et al., 2014a; Tilmes et al., 2019).

Simulated OA burdens also show a large spread among global models, with Gliß et al. (2021) reporting a multi-model median of 1.91 ±0.65 Tg for the year 2010. This large spread reflects the wide range in the complexity of the OA parameterizations, particularly for SOA formation, as well as in the primary OA emissions (Tsigaridis et al., 2014; Gliß et al., 2021). The uncertainties are particularly large in model estimates of SOA production rates, which vary between 10 and 143 Tg yr^{-1} (Tsigaridis et al., 2014; Hodzic et

ACCEPTED VERSION SUBJECT TO FINAL EDITING

al., 2016; Tilmes et al., 2019). While the level of complexity in the representation of OA in global models has increased since AR5 (Shrivastava et al., 2017; Hodzic et al., 2020) limitations in process level understanding of the formation, aging and removal of organic compounds lead to uncertainties in the global model predictions of global OA burden and distribution as well as the relative contribution of POA and SOA to OA. Jo et al. (2016) estimated that BrC contributes about 20% of total OA burden. That would give BrC a burden similar to that of BC (*low confidence*), enhancing the overall forcing exerted by carbonaceous aerosol absorption (Zhang et al., 2020).

In summary, the lack of global scale observations of carbonaceous aerosol, its complex atmospheric chemistry, and the large spread in its simulated global budget and burdens means that there is only *low confidence* in the quantification of the present-day atmospheric distribution of individual components of carbonaceous aerosols. Global trends in carbonaceous aerosols cannot be characterised due to limited observations, but sites representative of background conditions have reported multi-year declines in BC over several regions of the Northern Hemisphere.

6.3.6 Implications of SLCF abundances for Atmospheric Oxidizing Capacity

The atmospheric oxidising capacity is determined primarily by tropospheric hydroxyl (OH) radical and to a smaller extent by NO_3 radical, ozone, hydrogen peroxide (H_2O_2) and halogen radicals. OH is the main sink for many SLCFs, including methane, halogenated compounds (HCFCs and HFCs), CO and NMVOCs, controlling their lifetimes and consequently their abundance and climate influence. OH initiated oxidation of methane, CO and NMVOCs in the presence of NO_x leads to the production of tropospheric ozone. OH also contributes to the formation of aerosols from oxidation of SO_2 to sulphate and VOCs to secondary organic aerosols. The evolution of atmospheric oxidising capacity of the Earth driven by human activities and natural processes is, therefore, of significance for climate and air quality concerns.

The main source of tropospheric OH is the photoexcitation of tropospheric ozone that creates an electronically excited oxygen atom which reacts with water vapour producing OH. A secondary source of importance for global OH is the recycling of peroxy radicals formed by the reaction of OH with reduced and partly oxidized species, including methane, CO and NMVOCs. In polluted air, NO_x emissions control the secondary OH production, while in pristine air it occurs via other mechanisms involving, in particular, isoprene (Lelieveld et al., 2016; Wennberg et al., 2018). Knowledge of the effect of isoprene oxidation on OH recycling has evolved tremendously over the past decade facilitating mechanistic explanation of elevated OH concentrations observed in locations characterised by low NO_x levels (Hofzumahaus et al., 2009; Paulot et al., 2009; Peeters et al., 2009, 2014; Fuchs et al., 2013). Since AR5, inclusion of improved chemical mechanisms in some CTMs suggest advances in understanding of the global OH budget, however these improvements have yet to be incorporated in CMIP6-generation ESMs.

As a result of the complex photochemistry, tropospheric OH abundance is sensitive to changes in SLCF emissions as well as climate. Increases in methane, CO, NMVOCs reduce OH while increases in water vapour and temperature, incoming solar radiation, NO_x and tropospheric ozone enhance OH. The OH level thus responds to climate change and climate variability via its sensitivity to temperature and water vapour as well as the influence of climate on natural emissions (e.g., wetland methane emissions, lightning NO_x, BVOCs, fire emissions) with consequent feedbacks on climate (Section 6.4.5). Climate modes of variability, like ENSO, also contribute to OH variability via changes in lightning NO_x emissions and deep convection (Turner et al., 2018), and fire emissions (Rowlinson et al., 2019).

Global scale OH observations are non-existent because of its extremely short lifetime (~1 s) and therefore global OH abundance and its time variations are either inferred from atmospheric measurements of methyl chloroform (MCF) (Prinn et al., 2018 and references therein) or derived from global atmospheric chemistry models (Lelieveld et al., 2016). AR5 reported small interannual OH variations in the 2000s based on atmospheric inversions of MCF observations (within ±5%) and global CCMs and CTMs (within ±3%) (Ciais et al., 2013).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Since AR5, there is much closer agreement in the estimates of interannual variations in global mean OH derived from atmospheric inversions, empirical reconstruction, and global CCMs and ESMs with an estimate of 2 to 3% over the 1980 to 2015 period (Table 6.7). While the different methodologies agree on the occurrence of small inter-annual variations, there is much debate over longer term global OH trend. Two studies using multi-box model inversions of MCF and methane observations suggest large positive and negative trends since 1990s in global mean OH (Rigby et al., 2017; Turner et al., 2017), however, both find that observational constraints are weak such that a wide range of multi-annual OH variations are possible. Indeed, (Naus et al., 2019) find an overall positive global OH trend over the past two decades (Table 6.7) after accounting for uncertainties and biases in atmospheric MCF and CH_4 inversions confirming the weakness in observational constraints for deriving OH trends. Global ESMs, CCMs and CTMs exhibit stabilized or increasing global OH after 1980 contrary to the lack of trend derived from some atmospheric inversions and empirical reconstructions (Table 6.7). In particular, a three member ensemble of ESMs participating in the AerChemMIP/CMIP6 agrees that global OH has increased since 1980 by around 9% (Figure 6.9) with an associated reduction in methane lifetime (Stevenson et al., 2020). This positive OH trend is in agreement with the ~7% OH increase derived by assimilating global-scale satellite observations of CO over the 2002-2013 period (with CO declining trends) into a CCM (Gaubert et al., 2017; see section 6.3.4). Multi-model sensitivity analysis suggests that increasing OH since 1980 is predominantly driven by changes in anthropogenic SLCF emissions with complementary influence of increasing NO_x and decreasing CO emissions (Stevenson et al., 2020).

Over paleo time scales, proxy-based observational constraints from CH_4 and formaldehyde suggest tropospheric OH to be a factor of 2 to 4 lower in the last glacial maximum (LGM) relative to preindustrial levels, though these estimates are highly uncertain (Alexander and Mickley, 2015). Global models, in contrast, exhibit no change in tropospheric OH (and consequently in methane lifetime) at the LGM relative to the preindustrial (Murray et al., 2014; Quiquet et al., 2015), however the sign and magnitude of OH changes are sensitive to model predictions of changes in natural emissions, including lightning NO_x and BVOCs, and model representation of isoprene oxidation chemistry (Achakulwisut et al., 2015; Hopcroft et al., 2017).

Regarding change since preindustrial era, at the time of the AR5, ensemble mean of 17 global models participating in ACCMIP indicated little change in tropospheric OH from 1850 to 2000. This was due to the competing and finally offsetting changes in factors enhancing or reducing OH with a consequent small decline in methane lifetime (Naik et al., 2013; Voulgarakis et al., 2013). However, there was large diversity in both the sign and magnitude of past OH changes across the individual models attributed to disparate implementation of chemical and physical processes (Nicely et al., 2017; Wild et al., 2020). Analysis of historical simulations from three CMIP6 ESMs indicates little change in global mean OH from 1850 to about 1980 (Stevenson et al., 2020). However, there is no observational evidence of changes in global OH since 1850 up to early 1980s to evaluate the ESMs.

In summary, global mean tropospheric OH does not show a significant trend from 1850 up to around 1980 (*low confidence*). There is conflicting information from global models constrained by emissions versus observationally constrained inversion methods over the 1980-2014 period. A positive trend since 1980 (about 9 % increase over 1980-2014) is a robust feature among ESMs and CCMs and there is *medium confidence* that this trend is mainly driven by increases in global anthropogenic NO_x emissions and decreases in CO emissions. There is *limited evidence* and *medium agreement* for positive trends or absence of trends inferred from observation-constrained methods. Overall, there is *medium confidence* that global mean OH has remained stable or exhibited a positive trend since the 1980s.

6.4 SLCF radiative forcing and climate effects

The radiative forcing on the climate system introduced by SLCFs is distinguished from that of LLGHGs by the diversity of forcing mechanisms for SLCFs, and the challenges of constraining these mechanisms via observations and of inferring their global forcings from available data. Chapter 7 assesses the global estimates of ERFs due to SLCF abundance changes. This section assesses the characteristics (e.g., spatial patterns, temporal evolution) of forcings, climate response and feedbacks due to SLCFs relying primarily on results from CMIP6 models. Additionally, the ERFs for several aerosol-based forms of solar radiation modification (SRM) are discussed in Section 6.4.6.

Forcing and climate response due to changes in SLCFs are typically estimated from global models that vary in their representation of the various chemical, physical, and radiative processes (see Box 6.1) affecting the causal chain from SLCF emissions to climate response (Figure 6.2). The AR5 noted that the representation of aerosol processes varied greatly in CMIP5 models and that it remained unclear what level of sophistication is required to properly quantify aerosol effects on climate (Boucher et al., 2013). Since the AR5, (Ekman, 2014) found that the CMIP5 models with the most complex representations of aerosol impacts on cloud microphysics had the largest reduction in biases in surface temperature trends. CMIP6-generation CCMs that simulate aerosol and cloud size distributions better represent the effect of a volcanic eruption on lower atmosphere clouds than a model with aerosol-mass only (Malavelle et al., 2017). This highlights the need for skillful simulation of conditions underlying aerosol-cloud interactions, such as the distribution, transport and properties of aerosol species, in addition to the interactions themselves (see Chapter 7). In advance of CMIP6, representations of aerosol processes and aerosol-cloud interactions in ESMs have generally become more comprehensive (Gliß et al., 2021; Meehl et al., 2020; Thornhill et al., 2021b; see also Section 1.5), with enhanced links to aerosol emissions and gas-phase chemistry. Many CMIP6 models (see Annex II Table AII.5) now simulate aerosol number size distribution, in addition to mass distribution, which is a prerequisite for accurately simulating number concentrations of cloud condensation nuclei (CCN) (Bellouin et al., 2013) while some CMIP6 models use prescribed aerosol optical properties to constrain aerosol forcing (e.g., Stevens et al., 2017). Hence, the range of complexity in aerosol modeling noted in CMIP5 is still present in the CMIP6 ensemble. Although simulated CCN have been compared to surface (Fanourgakis et al., 2019) and aircraft (Reddington et al., 2017) measurements, with mixed results, the lack of global coverage limits confidence in the evaluations. Evaluations of aerosol optical depths have been more wide ranging (section 6.3.5; Gliß et al., 2021) but are less relevant to aerosol-cloud interactions as they do not allow to evaluate vertical profiles, aerosol-cloud overlap regions, aerosol type or number. Nevertheless, biases in simulated patterns and trends in aerosol optical depths, alongside biases in cloud fractions (Vignesh et al., 2020), likely affect quantifications of the aerosol-cloud interactions.

In summary, CMIP6 models generally represent more processes that drive aerosol-cloud interactions than the previous generation of climate models, but there is only *medium confidence* that those enhancements improve their fitness for the purpose of simulating radiative forcing of aerosol-cloud interactions because only a few studies have identified the level of sophistication required to do so. In addition, the challenge of representing the small-scale processes involved in aerosol-cloud interactions, and a lack of relevant model-data comparisons, does not allow to quantitatively assess the progress of the models from CMIP5 to CMIP6 in simulating the underlying conditions relevant for aerosol-cloud interactions at this time.

6.4.1 Historical Estimates of Regional Short-lived Climate Forcing

The highly heterogeneous distribution of SLCF abundances (section 6.3) translates to strong heterogeneity in

ACCEPTED VERSION SUBJECT TO FINAL EDITING

the spatial pattern and temporal evolution of forcing and climate responses due to SLCFs. This section assesses the spatial patterns of the current forcing due to aerosols and their historical evolution by region.

In AR5, the confidence in the spatial patterns of aerosol and ozone forcing was lower than that for the global mean because of the large spread in the regional distribution simulated by global models, and was assessed as 'medium'. The AR5 assessment was based on aerosol and ozone RFs and aerosol ERFs (with fixed SSTs) from ACCMIP and a small sample of CMIP5 experiments (Myhre et al., 2013b; Shindell et al., 2013). For this assessement, the spatial distribution of aerosol ERF (ERF_{AER}) due to human-induced changes in aerosol concentrations over 1850-2014 is quantified based on results from a 7 member ensemble of CMIP6 ESMs including interactive gas and aerosol chemistry analysed in AerChemMIP. There is insufficient information to estimate the spatial patterns of ozone ERF from CMIP6, however, the spatial patterns in SLCF ERF are dominated by that from aerosol ERF over most regions (e.g., Shindell et al., 2015). The ERF_{AER} includes contributions from both direct aerosol-radiation (ERF_{ari}) and indirect aerosol-cloud interactions (ERF_{aci}) (see Section 7.3.3) and is computed as the difference between radiative fluxes from simulations with time-evolving aerosol and their precuror emissions and identical simulations but with these emissions held at their 1850 levels (Collins et al., 2017). Both the simulations are driven by time-evolving SSTs and sea ice from the respective coupled model historical simulation and therefore differ from ERFs computed using fixed pre-industrial SST and sea-ice fields (Section 7.3.1), but the effect of this difference is generally small (Forster et al., 2016). A correction for land surface temperature change (Section 7.3.1) is not available from these data to explicitly quantify the contribution from adjustments. The ESMs included here used the CMIP6 anthropogenic and biomass burning emissions for ozone and aerosol precursors but varied in their representation of natural emissions, chemistry and climate characteristics contributing to spread in the simulated concentrations (also see section 6.3) and resulting forcings, partly reflecting uncertainties in the successive processes (Thornhill et al., 2021b).

The geographical distribution of the ensemble mean ERF_{AER} over the 1850-2014 period is highly heterogeneous (Figure 6.10a) in agreement with AR5. Negative ERF_{AER} is greatest over and downwind of most industrialized regions in the Northern Hemisphere and to some extent over tropical biomass burning regions, with robust signals. Largest negative forcing occurs over East Asia and South Asia, followed by Europe and North America, reflecting the changes in anthropogenic aerosol emissions in the recent decades (Section 6.2). Positive ERF_{AER} over high albedo areas, including cryosphere, deserts and clouds, also found in AR5 and attributed to absorbing aerosols, are not robust across the small CMIP6 ensemble applied here. Regionally aggregated shortwave (SW) and longwave (LW) components of the ERF_{AER} exhibit similar large variability across regions (Figure 6.10b). The SW flux changes come from aerosol-radiation and aerosol-cloud interactions while the small positive LW flux changes come from aerosol-cloud interactions (related to liquid water path changes (Section 7.3.2.2). These spatial patterns in ERF_{AER} are similar to the patterns reported in AR5.

Time evolution of 20 year means of regional net ERF_{AER} shows that the regions are divided into two groups depending on whether the mean ERF_{AER} attains its negative peak value in the 1970s to 1980s (e.g., Europe, North America) or in the late 1990s to 2000s (e.g., Asia, South America) (Figure 6.11). Qualitatively, this shift in the distribution of ERF_{AER} trends is consistent with the regional long-term trends in aerosol precursor emissions (Section 6.21; Figures 6.18 and 6.19) and their abundances (Section 6.3). However, at finer regional scales, there are regions where sulphate aerosols are still following an upward trend (e.g., South Asia; see Section 6.3.5) implying that the trends in ERF_{AER} may not have shifted for these regions. The continental scale ERF_{AER} trends are also in line with the satellite-observed AOD trends assessed in Section 2.2.6. Global mean ERF_{AER} reaches maximum negative values in the mid-1970s and its magnitude gradually decreases thereafter. This weakening of the negative forcing since 1990 agrees with findings by who attribute this to a reduction in global mean SO_2 emissions combined with an increase in global BC (Myhre et al., 2017). Uncertainties in model simulated aerosol ERF distribution and trends can result from intermodel variations in the representation of aerosol-cloud interactions and aerosol microphysical processes as also demonstrated by Bauer et al., (2020).

In summary, the spatial and temporal distribution of the net aerosol ERF from 1850 to 2014 is highly heterogeneous (*high confidence*). Globally, there has been a shift from increase to decrease of the negative

ACCEPTED VERSION SUBJECT TO FINAL EDITING

net aerosol ERF driven by trends in aerosol and their precursor emissions (*high confidence*). However, the timing of this shift varies by continental-scale region and has not occured for some finer regional scales.

[START FIGURE 6.10 HERE].

Figure 6.10: Multi-model mean Effective radiative forcings (ERFs) due to aerosol changes between 1850 and recent-past (1995-2014). Panel (a) shows the spatial distribution of the net ERF with area-weighted global mean ERF shown at the lower right corner. Uncertainty is represented using the advanced approach: No overlay indicates regions with robust signal, where ≥66% of models show change greater than variability threshold and ≥80% of all models agree on sign of change; diagonal lines indicate regions with no change or no robust signal, where <66% of models show a change greater than the variability threshold; crossed lines indicate regions with conflicting signal, where ≥66% of models show change greater than variability threshold and <80% of all models agree on sign of change. For more information on the advanced approach, please refer to the Cross-Chapter Box Atlas.1. Panel (b) shows the mean shortwave and longwave ERF for each of the 14 regions defined in the Atlas. Violins in panel (b) show the distribution of values over regions where ERFs are significant. ERFs are derived from the difference between top of the atmosphere (TOA) radiative fluxes for Aerosol Chemistry Model Intercomparison Project (AerChemMIP) experiments histSST and histSST-piAer (Collins et al., 2017) averaged over 1995-2014 (Box 1.4, Chapter 1). The results come from 7 Earth System Models: MIROC6, MPI-I-ESM-1-2-HAM, MRI-ESM2-0, GFDL-ESM4, GISS-E2-1-G, NorESM2-LM, and UKESM-0-LL. These data can be seen in the Interactive Atlas. Further details on data sources and processing are available in the chapter data table (Table 6.SM.1).

[END FIGURE 6.10 HERE]

[START FIGURE 6.11 HERE]

Figure 6.11: Time evolution of 20-year multi-model mean averages of the annual area-weighted mean regional net Effective Radiative Forcings (ERFs) due to aerosols. Each of the 14 major regions in the Atlas are shown, as well as the global mean, using the models and model experiments as in Figure 6.10. Further details on data sources and processing are available in the chapter data table (Table 6.SM.1).

[END FIGURE 6.11 HERE]

6.4.2 Emission-based Radiative Forcing and effect on GSAT

The ERFs attributable to emissions versus concentrations for several SLCFs including ozone and methane are different. A concentration change, used to assess the abundance-based ERF, results from the changes in emissions of multiple species and subsequent chemical reactions. The corollary is that the perturbation of a single emitted compound can induce subsequent chemical reactions and affect the concentrations of several climate forcers (chemical adjustments), this is what is accounted for in emission-based ERF. Due to non-linear chemistry (cf. Section 6.3) and non-linear aerosol-cloud interactions (section 7.3.3.2), the ERF attributed to the individual species cannot be precisely defined, and can only be estimated through model simulations. For example, the ERF attributed to methane emissions, which includes indirect effects through ozone formation and oxidation capacity with feedbacks on the methane lifetime, depend non-linearly on the concentrations of NO_x, CO and VOCs. This means that the results from the model simulations depend to some extent on the chosen methodology. In AR5 (based on Shindell et al., 2009; Stevenson et al., 2013) the attribution was done by removing the anthropogenic emissions of individual species one-by-one from a control simulation for present day conditions. Further, only the radiative forcings, and not the ERF (mainly including the effect of aerosol-cloud interactions) were attributed to the emitted compounds.

Since AR5, the emission estimates have been revised and extended for CMIP6 (Hoesly et al., 2018), the models have been further developed, the period has been extended (1750-2019, vs 1750-2011 in AR5) and the experimental setup for the model simulations has changed (Collins et al., 2017) making a direct

ACCEPTED VERSION SUBJECT TO FINAL EDITING

comparison of results difficult. Figure 6.13 shows the global and annual mean ERF attributed to emitted compounds over the period 1750-2019 based on AerChemMIP simulations (Thornhill et al., 2021b) where anthropogenic emissions or concentrations of individual species were perturbed from 1850 levels to 2014 levels (methodology described in Supplementary Material 6.SM.1).

[START FIGURE 6.12 HERE]

Figure 6.12: Contribution to effective radiative forcing (ERF) (left) and global mean surface air temperature (GSAT) change (right) from component emissions between 1750 to 2019 based on CMIP6 models (Thornhill et al., 2021b). ERFs for the direct effect of well-mixed greenhouse gases (WMGHGs) are from the analytical formulae in section 7.3.2, H_2O (strat) is from Table 7.8. ERFs for other components are multi-model means from Thornhill et al. (2021b) and are based on ESM simulations in which emissions of one species at a time are increased from 1850 to 2014 levels. The derived emission-based ERFs are rescaled to match the concentration-based ERFs in Figure 7.6. Error bars are 5-95% and for the ERF account for uncertainty in radiative efficiencies and multi-model error in the means. ERF due to aerosol-radiation (ERFari) and cloud effects are calculated from separate radiation calls for clear-sky and aerosol free conditions (Ghan, 2013; Thornhill et al., 2021b). "Cloud" includes cloud adjustments (semi-direct effect) and indirect aerosol-cloud interactions (ERFaci). The aerosol components (SO_2, organic carbon, black carbon) are scaled to sum to -0.22 W m^{-2} for ERFari and -0.84 W m^{-2} for "cloud" (section 7.3.3). For GSAT estimates, time series (1750-2019) for the ERFs have been estimated by scaling with concentrations for WMGHGs and with historical emissions for SLCFs. The time variation of ERFaci for aerosols is from Chapter 7. The global mean temperature response is calculated from the ERF time series using an impulse response function (see Cross-Chapter Box 7.1) with a climate feedback parameter of -1.31 W m^{-2} $°C^{-1}$. Further details on data sources and processing are available in the chapter data table (Table 6.SM.1).

[END FIGURE 6.12 HERE]

The ERF based on primary CO_2 emissions is slightly lower than the abundance-based estimate (section 7.3.2.1) because the abundance-based ERF combines the effect of primary CO_2 emissions and a small additional secondary contribution from atmospheric oxidation of CH_4, CO, and VOCs (4%) of fossil origin, consistent with AR5 findings.

Ozone depleting substances, such as N_2O and halocarbons, cause a reduction in stratospheric ozone, which affects ozone and OH production in the troposphere through radiation UV changes (and thus affect methane). They also have indirect effects on aerosols and clouds (Karset et al., 2018) since changes in oxidants induce changes in the oxidation of aerosol precursors.

The net ERF from N_2O emissions is estimated to be 0.24 (0.13 to 0.34) W m^{-2}, which is very close to the abundance-based estimate of 0.21 W m^{-2} (Section 7.3.2.3). The indirect contributions from N_2O are relatively minor with negative (methane lifetime) and positive (ozone and clouds) effects nearly compensating each other. Emissions of halogenated compounds, including CFCs and HCFCs, were assessed as very likely causing a net positive ERF in the AR5. However recent studies (Morgenstern et al., 2020; O'Connor et al., 2021; Thornhill et al., 2021b) find strong adjustments in Southern Hemisphere aerosols and clouds such that the *very likely* range in the emission based ERF for CFC+HCFCs+HFCs now also include negative values.

For methane emissions, in addition to their direct effect, there are indirect positive ERFs from methane enhancing its own lifetime, causing ozone production, enhancing stratospheric water vapor, and influencing aerosols and the lifetimes of HCFCs and HFCs (Myhre et al., 2013b; O'Connor et al., 2021). The ERF from methane emissions is considerably higher than the ERF estimate resulting from its abundance change. The central estimate with the *very likely* range is 1.21 (0.90 to 1.51) W m^{-2} for emission-based estimate versus 0.54 W m^{-2} for abundance-based estimate (cf. section 7.3.5). The abundance-based ERF estimate for CH_4 results from contributions of its own emissions and the effects of several other compounds, some decreasing CH_4 lifetime, notably NO_x, which importantly reduce the CH_4 abundance-based ERF. Emissions of CO and

ACCEPTED VERSION SUBJECT TO FINAL EDITING

NMVOCs both indirectly contribute to a positive ERF through enhancing ozone production in the troposphere and increasing the methane lifetime. For CO and NMVOCs of fossil origin there is also a 0.07 W m^{-2} contribution to CO_2 from their oxidation. The *very likely* total ERF of CO and NMVOCs emissions is estimated to 0.45 (0.22 to 0.67) W m^{-2}.

NO_x causes a positive ERF through enhanced tropospheric ozone production and a negative ERF through enhanced OH concentrations that reduce the methane lifetime. There is also a small negative ERF contribution through formation of nitrate aerosols, although only 3 of the AerChemMIP models include nitrate aerosols. The best estimate of the net ERF from changes in anthropogenic NO_x emissions is -0.29 (-0.57 to 0.0) W m^{-2}. The magnitude is somewhat greater than the AR5 estimate (-0.15 (-0.34 to + 0.02) W m^{-2}) but with similar level of uncertainty. The difference between AR6 and AR5 estimates is possibly due to the different modeling protocols (see Supplementary Material 6.SM.1).

Anthropogenic emissions of SO_2 lead to formation of sulphate aerosols and a negative ERF through aerosol-radiation and aerosol-cloud interactions. The emission-based ERF_{aci}, which was not previously considered in AR5, is now included. The estimated ERF is thus considerably more negative than the AR5 estimate with a radiative forcing of -0.4 W m^{-2}, despite the decline of ERF due to aerosols since 2011 (Figure 6.12, Section 7.3.3.1.3). SO_2 emissions are estimated to contribute to a negative ERF of -0.90 (-0.24 to -1.56) W m^{-2}, with -0.22 W m^{-2} from aerosol-radiation interactions and -0.68 W m^{-2} from aerosol-cloud interactions. Emissions of NH_3 lead to formation of ammonium-nitrate aerosols with an estimated ERF of -0.03 W m^{-2}.

The best estimate for the ERF due to emissions of BC is reduced from the AR5, and is now estimated to be 0.063 (-0.28 to 0.42) W m^{-2} with an uncertainty also including negative values. As discussed in Section 7.3.3.1.2, a significant portion of the positive BC forcing from aerosol-radiation interactions is offset by negative atmospheric adjustments due to cloud changes as well as lapse rate and atmospheric water vapor changes, resulting in a smaller positive net ERF for BC compared with AR5. The large range in the forcing estimate stems from variation in the magnitude and sign of atmospheric adjustments across models and is related to the differences in the model treatment of different processes affecting BC (e.g., ageing, mixing) and its interactions with clouds and cryosphere (Thornhill et al., 2021b and Section 7.3.3.). The emission-based ERF for organic carbon aerosols is -0.20 (-0.03 to -0.41) W m^{-2}, a weaker estimate compared with AR5 attributed to stronger absorption by OC (section 7.3.3.1.2).

The emission-based contributions to GSAT change (Figure 6.12) were not assessed in AR5, but with the ERF from aerosol-cloud interactions attributed to the emitted compounds there is now a better foundation for this assessment. The contribution to emissions-based ERF at 2019 (left panel in figure 6.12) is scaled by the historical emissions (over the period 1750 to 2019) of each compound to reconstruct the historical time series of ERF. An impulse response function (see Cross-Chapter Box 7.1 and Supplementary Material 7.SM5.2) is then applied to obtain the contribution of SLCF emissions to the GSAT response. Due to the non-linear chemical and physical processes described above relating emissions to ERF, and the additional non-linear relations between ERF and GSAT, these emission-based estimates of GSAT responses strongly depend on the methodology applied to estimate ERF and GSAT (see Supplementary Material 6.SM.2). Therefore, the relative contribution of each compound through its primary emissions versus secondary formation or destruction (e.g. for methane emissions its ozone versus methane contributions), by construction (omitting the non-linear processes), will be equal for ERF and GSAT. Uncertainties in the GSAT response are estimated using the assessed range of the ECS from Chapter 7 of this report. For most of the SLCFs the uncertainty in the GSAT response is dominated by the uncertainty in the relationship between emissions and the ERF.

The contributions from the emitted compounds to GSAT broadly follow their contributions to the ERF, mainly because their evolution over the past decades have been relatively similar and slow enough compared to their lifetimes to be reflected similarly in their ERF and GSAT despite the delay of the GSAT response to ERF changes (see Section 6.6.1). However, for some SLCFs, e.g. SO_2, that have been reduced globally, their contribution to GSAT change is slightly higher compared with that of CO_2 than their relative contribution to ERF because the peak in their ERF change has already occurred (see Section 6.4.1) whereas the peak of their GSAT effect started to decline recently (see also Figure 7.9). This is due to the inertia of the climate system

ACCEPTED VERSION SUBJECT TO FINAL EDITING

delaying the full response of GSAT to a change in forcing (Figure 6.15).

In summary, emissions of SLCFs, especially CH_4, NO_x and SO_2, have substantial effects on effective radiative forcing (ERF) (*high confidence*). The net global emissions-based ERF of NO_x is negative and that of NMVOCs is positive, in agreement with the AR5 assessment (*high confidence*). For methane, the emission-based ERF is twice as high as the abundance-based ERF (*high confidence*). SO_2 emissions make the dominant contribution to the ERF associated with the aerosol–cloud interaction (*high confidence*)**.** The contributions from the emitted compounds to GSAT broadly follow their contributions to the ERF (*high confidence*). However, due to the inertia of the climate system delaying the full GSAT response to a change in forcing, the contribution to GSAT change due to SO_2 emission is slightly higher compared with that due to CO_2 emissions (than their relative contributions to ERF) because the peak in emission-induced SO_2 ERF has already occurred.

6.4.3 Climate responses to SLCFs

This section briefly discusses the climate response to SLCFs, in particular to changes in aerosols, and gathers complementary information and assessments from Chapters 3, 7, 8, and 10.

Warming or cooling atmospheric aerosols, such as BC and sulphate, can affect temperature and precipitation in distinct ways by modifying the shortwave and longwave radiation, the lapse rate of the troposphere, and influencing cloud microphysical properties (see Box 8.1 and Section 10.1.4.1.4). An important distinction between scattering and absorbing aerosols is the opposing nature of their influences on circulation, clouds, and precipitation, besides surface temperature as evident from the contrasting regional climate responses to regional aerosol emissions (e.g., Lewinschal et al., 2019; Sand et al., 2020; also see Chapters 8 and 10).

On the global scale, as assessed in Chapter 3, anthropogenic aerosols have *likely* cooled GSAT since 1850–1900 driven by the negative aerosol forcing, while it is *extremely likely* that human-induced stratospheric ozone depletion has primarily driven stratospheric between 1979 and the mid-1990s. Multiple modelling studies support the understanding that present-day emissions of SO_2, precursor for sulphate aerosols, are the dominant driver of near-surface air temperature in comparison to BC or OC even though, for some regions, BC forcing plays a key role (Baker et al., 2015; Samset et al., 2016; Stjern et al., 2017; Zanis et al., 2020)**.** Further, there is *high confidence* that the aerosol-driven cooling has led to detectable large-scale water cycle changes since at least the mid-20th century as assessed in Chapter 8. The overall effect of surface cooling from anthropogenic aerosols is to reduce global precipitation and alter large-scale atmospheric circulation patterns (*high confidence*), primarily driven by the cooling effects of sulphate aerosols (Section 8.2.1). In addition, there is *high confidence* that darkening of snow through the deposition of black carbon and other light absorbing particles enhances snow melt (SROCC Chapter 3, see also Section 7.3.4.3).

In AR5, there was low confidence in the overall understanding of climate response to spatially varying patterns of forcing, though there was medium to high confidence in some regional climate responses, such as the damped warming of the NH and shifting of the ITCZ from aerosols, and positive feedbacks enhancing the local response from high-latitude snow and ice albedo changes. Since AR5, the relationship between inhomogeneous forcing and climate response is better understood providing further evidence of the climate influence of SLCFs (aerosols and ozone in particular) on global to regional scales (Collins et al., 2013; Shindell et al., 2015; Aamaas et al., 2017; Kasoar et al., 2018; Persad and Caldeira, 2018; Wilcox et al., 2019) which differ from the relatively homogeneous spatial influence from LLGHGs.

Large geographical variations in aerosol ERFs (section 6.4.1) affect global and regional temperature responses (Shindell et al., 2015, Myhre et al., 2013a). A multimodel CMIP6 ensemble mean results (Figure 6.13) show cooling over almost all areas of the globe in response to increases of aerosol and their precursor emissions from 1850 to recent past (1995–2014). While the ERF has hotspots, the temperature response is more evenly distributed in line with the results of CMIP5 models including the temperature response to ozone changes (Shindell et al 2015). The ensemble mean global mean surface temperature decreases by 0.66±0.51 °C while decreasing by 0.97±0.54 °C for Northern Hemisphere and 0.34±0.2 °C for Southern

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Hemisphere. The zonal mean temperature response is negative at all latitudes (high confidence) and becomes more negative with increasing latitude, with a maximum ensemble mean decrease of around 2.7 °C at Northern polar latitudes. The zonal mean response is not directly proportional to the zonal mean forcing, especially in the Arctic where the temperature response is cooling while the local ERF is positive (6.10). This is consistent with prior studies showing that the Arctic, in particular, is highly sensitive to forcing at NH midlatitudes (e.g., Sand et al., 2013b; Shindell and Faluvegi, 2009) and with results from CMIP5 models (Shindell et al., 2015) (more on Arctic below). Thus, there is *high confidence* that the temperature response to aerosols is more asymmetric than the response to WMGHGs and negative at all latitudes.

The asymmetric aerosol and greenhouse gas forcing on regional scale climate responses have also been assessed to lead to contrasting effects on precipitation in Chapter 8. The asymmetric historical radiative forcing due to aerosols led to a southward shift in the tropical rain belt (*high confidence*) and contributed to the Sahel drought from the 1970s to the 1980s (*high confidence*). Furthermore, the asymmetry of the forcing led to contrasting effects in monsoon precipitation changes over West Africa, South Asia and East Asia over much of the mid-20th century due to GHG-induced precipitation increases counteracted by anthropogenic aerosol-induced decreases (*high confidence*) (see Section 8.3, Box 8.1).

The Arctic region is warming considerably faster than the rest of the globe (Atlas 5.9.2.2) and, generally, studies indicate that this amplification of the temperature response toward the Arctic has important contribution from local and remote aerosol forcing (Stjern et al., 2017; Westervelt et al., 2018). Several studies indicate that changes in long-range transport of sulphate and BC from northern midlatitudes can potentially explain a significant fraction of Arctic warming since 1980s (e.g., Breider et al., 2017; Navarro et al., 2016; Ren et al., 2020). Modeling studies show that changes in midlatitude aerosols have influenced Arctic climate by changing the radiative balance through aerosol-radiation and aerosol-cloud interactions and enhancing poleward heat transport (Navarro et al., 2016; Ren et al., 2020b). Idealized aerosol perturbation studies have shed further light on the sensitivity of Arctic temperature response to individual aerosol species. Studies show relatively large responses in the Arctic to BC perturbations and reveal the importance of remote BC forcing by rapid adjustments (Sand et al., 2013a; Stjern et al., 2017; Liu et al., 2018; Yang et al., 2019a). Perturbations in SO_2 emissions over major emitting regions in the Northern Hemisphere have been shown to produce largest Arctic temperature responses (Kasoar et al., 2018; Lewinschal et al., 2019).

The effects of changes in aerosols on local and remote changes in temperature, circulation and precipitation are sensitive to a number of model uncertainties affecting aerosol sources, transformation, and resulting climate effects. Therefore, regional climate effects in global model studies must be interpreted with caution. When investigating the climate response to regional aerosol emissions, such uncertainties are likely to be confounded even further by the variability between models in regional climate and circulation patterns, leading to greater intermodel spread at regional scales than at a global scale (Baker et al., 2015; Kasoar et al., 2016).

In summary, over the historical period, changes in aerosols and their ERF have primarily contributed to cool the surface temperature partly masking the human-induced warming (*high confidence*). Radiative forcings induced by aerosol changes lead to both local and remote changes in temperature (*high confidence*). The temperature response preserves hemispheric asymmetry of the ERF but is more latitudinally uniform with strong amplification of the temperature response towards the Arctic (*medium confidence*).

[START FIGURE 6.13 HERE]

Figure 6.13: Multi-model mean surface air temperature response due to aerosol changes between 1850 and recent-past (1995-2014). Calculation is based on the difference between CMIP6 'historical' and AerChemMIP 'hist-piAer' experiments, where a) is the spatial pattern of the annual mean surface air temperature response, and b) is the mean zonally averaged response. Model means are derived from years 1995-2014. Uncertainty is represented using the advanced approach: No overlay indicates regions with robust signal, where ≥66% of models show change greater than variability threshold and ≥80% of all models agree on sign of change; diagonal lines indicate regions with no change or no robust signal, where <66% of models show a change greater than the variability threshold; crossed lines indicate regions with

ACCEPTED VERSION SUBJECT TO FINAL EDITING

conflicting signal, where ≥66% of models show change greater than variability threshold and <80% of all models agree on sign of change. For more information on the advanced approach, please refer to the Cross-Chapter Box Atlas.1. AerChemMIP models MIROC6, MRI-ESM2-0, NorESM2-LM, GFDL-ESM4, GISS-E2-1-G, UKESM1-0-LL are used in the analysis. Further details on data sources and processing are available in the chapter data table (Table 6.SM.1).

[END FIGURE 6.13 HERE]

6.4.4 Indirect radiative forcing through effects of SLCFs on the carbon cycle

Deposition of reactive nitrogen (Nr) (i.e. NH_3 and NO_x) increases the plant productivity and carbon sequestration in N-limited forests and grasslands, and also in open and coastal waters and open ocean. Such inadvertent fertilization of the biosphere can lead to eutrophication and reduction in biodiversity in terrestrial and aquatic ecosystems. AR5 assessed that it is *likely* that Nr deposition over land currently increases natural CO_2 sinks, in particular in forests, but the magnitude of this effect varies between regions (Ciais et al., 2013). Increasing Nr deposition or the synergy between increasing Nr deposition and atmospheric CO_2 concentration could have contributed to the increasing global net land CO_2 sink [Section 5.2.1.4.1].

Ozone uptake itself damages photosynthesis and reduces plant growth with consequences for the carbon and water cycles (Ainsworth et al., 2012; Emberson et al., 2018). AR5 concluded there was robust evidence of the effect of ozone on plant physiology and subsequent alteration of the carbon storage but considered insufficient quantification of and a lack of systematic incorporation of the ozone effect in carbon-cycle models as a limitation to assess the terrestrial carbon balance (Ciais et al., 2013). Since AR5 several more ESMs have incorporated interactive ozone-vegetation damage resulting in an increase in evidence to support the influence of ozone on the land carbon cycle. The new modelling studies tend to focus on ozone effects on plant productivity rather than the land carbon storage and agree that ozone-induced gross-primary productivity (GPP) losses are largest today in eastern USA, Europe and eastern China ranging from 5-20% on the regional scale (Yue and Unger, 2014; Lombardozzi et al., 2015; Yue et al., 2017; Oliver et al., 2018) (*low confidence*). There is *medium evidence* and *high agreement* based on observational studies and models that ozone-vegetation interactions further influence the climate system, including water and carbon cycles by affecting stomatal control over plant transpiration of water vapour between the leaf surface and atmosphere (Arnold et al., 2018; Hoshika et al., 2015; Lombardozzi et al., 2013; Sun et al., 2012; VanLoocke et al., 2012; Wittig et al., 2007). While some modelling studies suggest that the unintended Nr deposition fertilization effect in forests may potentially offset the ozone-induced carbon losses (Felzer et al., 2007; de Vries et al., 2017), complex interactions have been observed between ozone and Nr deposition to ecosystems that have not yet been included in ESMs. For some plants, the effects of increasing ozone on root biomass become more pronounced as Nr deposition increased, and the beneficial effects of Nr on root development were lost at higher ozone treatments (Mills et al., 2016). Reducing uncertainties in ozone vegetation damage effects on the carbon cycle requires improved information on the sensitivity of different plant species to ozone, and measurements of ozone dose-response relationships for tropical plants, which are currently lacking. Surface ozone effect on the land carbon sink and indirect CO_2 forcing, therefore, remains uncertain. Collins et al. (2010) showed that adding in the effects of surface ozone on vegetation damage and reduced uptake of CO_2 added about 10 % to the methane emission metrics and could change the sign of the NO_x metrics. However, this estimate has to be considered as an upper limit due to limitation of the paramaterization used by Sitch et al. (2007) considering more recent knowledge and is thus not included in the current metrics (Section 7.6.1.3).

Tropospheric aerosols influence the land and ocean ecosystem productivity and the carbon cycle through changing physical climate and meteorology (Jones, 2003; Cox et al., 2008; Mahowald, 2011; Unger et al., 2017) and through changing deposition of nutrients including nitrogen, sulphur, iron and phosphorous (Mahowald et al., 2017; Kanakidou et al., 2018). There is *high evidence* and *high agreement* from field (Oliveira et al., 2007; Cirino et al., 2014; Rap et al., 2015; Wang et al., 2018c) and modelling (Mercado et al., 2009; Strada and Unger, 2016; Lu et al., 2017; Yue et al., 2017) studies that aerosols affect plant productivity through increasing the diffuse fraction of downward shortwave radiation although the

ACCEPTED VERSION SUBJECT TO FINAL EDITING

magnitude and importance to the global land carbon sink is controversial. At large-scales the dominant effect of aerosols on the carbon cycle is *likely* a global cooling effect of the climate (Jones, 2003; Mahowald, 2011; Unger et al., 2017) (*medium confidence*). We assess that these interactions between aerosols and the carbon cycle are currently too uncertain to constrain quantitatively the indirect CO_2 forcing.

In summary, reactive nitrogen, ozone and aerosols affect terrestrial vegetation and carbon cycle through deposition and effects on large scale radiation (*high confidence*) but the magnitude of these effects on the land carbon sink, ecosystem productivity and indirect CO_2 forcing remain uncertain due to the difficulty in disentangling the complex interactions between the effects. As such we assess it to be of second order in comparison to the direct CO_2 forcing (*high confidence*) but, at least for ozone, it could add a substantial (positive) forcing compared with its direct forcing (*low confidence*).

6.4.5 Non-CO_2 biogeochemical feedbacks

Climate change-induced changes in atmospheric composition and forcing due to perturbations in natural processes constitute an Earth system feedback amplifying (positive feedback) or diminishing (negative feedback) the initial climate perturbation (Ciais et al., 2013; Heinze et al., 2019). Quantification of these biogeochemical feedbacks is important to allow for better estimate of the expected effects of emission reduction policies for mitigating climate change and the effect on the allowable global carbon budget (Lowe and Bernie, 2018). Biogeochemical feedbacks due to changes in carbon-cycle are assessed in Section 5.4.5, while physical and biophysical climate feedbacks are assessed in Section 7.4.2. Additionally, non-CO_2 biogeochemical feedbacks due to climate driven changes in methane sources and N_2O sources and sinks are assessed in Section 5.4.7. The goal of this section is to estimate the feedback parameter (α as defined in section 7.4.1.1) from climate-induced changes in atmospheric abundances or lifetimes of SLCFs mediated by natural processes or atmospheric chemistry. These non-CO_2 biogeochemical feedbacks act on time scales of years to decades and have important implications for climate sensitivity and emission abatement policies. The feedback parameter is quantified entirely from ESMs that expand the complexity of CCMs by coupling the physical climate and atmospheric chemistry to land and ocean biogeochemistry. In AR5, α for non-CO_2 biogeochemical feedbacks was estimated from an extremely limited set of modeling studies with much less confidence associated with the estimate. Since AR5, ESMs have advanced to include more feedback processes facilitating a relatively more robust assessment of α. CMIP6 ESMs participating in AerChemMIP performed coordinated sets of experiments (Collins et al., 2017) facilitating the consistent estimation of α (Thornhill et al., 2021a) and we rely on this multi-model analysis for the best estimates (Table 6.9). Considering the consistent methodology, the assessed central values and 5-95% ranges for α are based on the AerChemMIP estimates. The full range of model uncertainty is not captured in AerChemMIP because of the relatively small ensemble size therefore estimates from studies using other models or with different protocols are discussed to reinforce or critique these values.

Climate-Sea-spray feedback: Sea-spray emissions from ocean surfaces influence climate directly or indirectly through the formation of CCN as discused in Section 6.2.1.2. They are sensitive to sea-surface temperature, sea ice extent, as well as wind speed and are therefore expected to feedback on climate (Struthers et al., 2013). However, there are large uncertainties in the strength of climate feedback from sea-spray aerosols because of the diversity in the model representation of emissions (many represent sea-salt emissions only) and their functional dependence on environmental factors noted above, in situ atmospheric chemical and physical processes affecting the sea-spray lifetime, and aerosol-cloud interactions (Struthers et al., 2013; Soares et al., 2016; Nazarenko et al., 2017). Additional work is needed to identify how sea-spray and POA emissions respond to shifts in ocean biology and chemistry in response to warming, ocean acidification, and changes in circulation patterns (Burrows et al., 2018) and affect CCN and INP formation (DeMott et al., 2016). AerChemMIP models, representing only the sea-salt emissions, agree that the sea-salt-climate feedback is negative, however there is a large range in the feedback parameter indicating large uncertainties (Table 6.9).

Climate-DMS feedback: Dimethyl sulphide (DMS) is produced by marine phytoplankton and is emitted to the atmosphere where it can lead to the subsequent formation of sulphate aerosol and CCN (see Section

ACCEPTED VERSION SUBJECT TO FINAL EDITING

6.2.1.2). Changes in DMS emissions from ocean could feedback on climate through their response to changes in temperature, solar radiation, ocean mixed-layer depth, sea-ice extent, wind-speed, nutrient recycling or shifts in marine ecosystems due to ocean acidification and climate change, or atmospheric processing of DMS into CCN (Heinze et al., 2019). Models with varying degrees of representation of the relevant biogeochemical processes and effects on DMS fluxes produce diverging estimates of changes in DMS emission strength under climate change resulting in large uncertainties in the DMS–sulphate–cloud albedo feedback (Bopp et al., 2004; Kloster et al., 2007; Gabric et al., 2013). In AR5, the climate-DMS feedback parameter was estimated to be -0.02 W m^{-2} °C^{-1} based on a single model. Since AR5, new modeling studies using empirical relationships between pH and total DMS production find that global DMS emissions decrease due to combined ocean acidification and climate change leading to a strong positive climate feedback (Six et al., 2013; Schwinger et al., 2017). However, another study argues for a much weaker positive feedback globally due to complex and compensating regional changes in marine ecosystems (Wang et al., 2018b). The AerChemMIP multimodel analysis suggests small positive feedback (Table 6.9), consistent with these recent studies, but with large uncertainties in the magnitude of α.

Climate-dust feedback: Mineral dust is the most abundant aerosol type in the atmosphere, when considering aerosol mass, and affects the climate system by interacting with both longwave and shortwave radiation as well as contributing to the formation of CCN and INP. Because dust emissions are sensitive to climate variability (e.g., through changes in the extent of arid land) (Section 6.2.1.2), it has been hypothesized that the climate-dust feedback could be an important feedback loop in the climate system. Since AR5, an improved understanding of the shortwave absorption properties of dust as well as a consensus that dust particles are larger than previously thought has led to a revised understanding that the magnitude of radiative forcing due to mineral dust is small (Kok et al., 2017; Ryder et al., 2018). A recent study notes that global models underestimate the amount of coarse dust in the atmosphere and accounting for this limitation raises the possibility that dust emissions warm the climate system (Adebiyi and Kok, 2020). Model predictions of dust emissions in response to future climate change range from an increase (Woodward et al., 2005) to a decrease (Mahowald and Luo, 2003), thus leading to high uncertainties on the sign of the climate-dust feedback. Since the AR5, Kok et al. (2018) estimated the direct dust-climate feedback parameter, from changes in the dust direct radiative effect only, to be in the range –0.04 to +0.02 W m^{-2} °C^{-1}. The assessed central value and the 5-95%range of climate-dust feedback parameter based on AerChemMIP ensemble (Table 6.9) is within the range of the published estimate, however both the magnitude and sign of α are model-dependent.

Climate-ozone feedback: Changes in ozone concentrations in response to projected climate change have been shown to lead to a potential climate-atmospheric chemistry feedback. Chemistry-climate models consistently project a decrease in lower tropical stratospheric ozone levels due to enhanced upwelling of ozone poor tropospheric air associated with surface warming driven strengthening of the Brewer-Dobson circulation (Bunzel and Schmidt, 2013). Further, models project an increase in middle and extratropical stratospheric ozone due to increased downwelling through the strengthened Brewer-Dobson circulation (Bekki et al., 2013; Dietmüller et al., 2014). These stratospheric ozone changes induce a net negative global mean ozone radiative feedback (Dietmüller et al., 2014). Tropospheric ozone shows a range of responses to climate with models generally agreeing that warmer climate will lead to decreases in the tropical lower troposphere owing to increased water vapour and increases in the sub-tropical to mid-latitude upper troposphere due to increases in lightning and stratosphere-to-troposphere transport (Stevenson et al., 2013). A small positive feedback is estimated from climate-induced changes in global mean tropospheric ozone (Dietmüller et al., 2014) while a small negative feedback is estimated by (Heinze et al., 2019) based on the model results of (Stevenson et al., 2013). Additionally, these ozone feedbacks induce a change in stratospheric water vapor amplifying the feedback due to stratospheric ozone (Stuber et al., 2001). Since AR5, several modeling studies have estimated the intensity of meteorology driven ozone feedbacks on climate from either combined tropospheric and stratospheric ozone changes or separately with contrasting results. One study suggests no change (Marsh et al., 2016), while other studies report reductions of equilibrium climate sensitivity ranging from 7-8% (Dietmüller et al., 2014; Muthers et al., 2014) to 20% (Nowack et al., 2015). The estimate of this climate-ozone feedback parameter is very strongly model dependent with values ranging from -0.13 to -0.01 W m^{-2} °C^{-1} though there is agreement that it is negative. The assessed central value and the 5-95% range of climate-ozone feedback parameter based on

ACCEPTED VERSION SUBJECT TO FINAL EDITING

AerChemMIP ensemble is within the range of these published estimates but closer to the lower bound. This climate-ozone feedback factor does not include the feedback on ozone from lightning changes which is discussed separately below.

Climate-BVOC feedback: BVOCs, such as isoprene and terpenes, are produced by land vegetation and marine plankton (Section 6.2.1.2). Once in the atmosphere, BVOCs and their oxidation products lead to the formation of secondary organic aerosols (SOA) exerting a negative forcing, and increased ozone concentrations and methane lifetime exerting a positive forcing. BVOC emissions are suggested to lead to a climate feedback in part because of their strong temperature dependence observed under present-day conditions (Kulmala et al., 2004; Arneth et al., 2010a). Their response to future changes in climate and CO_2 levels remains uncertain (see Section 6.2.2.3. Estimates of the climate-BVOC feedback parameter are typically based on global models which vary in their level of complexity of emissions parameterization, BVOC speciation, the mechanism of SOA formation and the interaction with ozone chemistry (Thornhill et al., 2021a). Since AR5, observational studies (Paasonen et al. 2013) and models (Scott et al. 2018) estimate the feedback due to biogenic SOA (via changes in BVOC emissions) to be in the range of about –0.06 to -0.01 W m^{-2} °C^{-1}. The assessed central estimate of the climate-BVOC feedback parameter based on the AerChemMIP ensemble suggests that climate-induced increases in SOA from BVOCs will lead to a strong cooling effect that will outweigh the warming from increased ozone and methane lifetime, however the uncertainty is large (Thornhill et al., 2021a).

Climate-Lightning NO_x feedback: As discussed in Section 6.2.1.2, climate change influences lightning NO_x emissions. Increases in lightning NO_x emissions will not only increase tropospheric ozone and decrease methane lifetime but also increase the formation of sulphate and nitrate aerosols, via oxidant changes, offsetting the positive forcing from ozone. The response of lightning NO_x to climate change remains uncertain and is highly dependent on the parameterization of lightning in ESMs (Finney et al., 2016b; Clark et al., 2017) (also see section 6.2.1.2). AerChemMIP multi-model ensemble mean estimate a net negative climate feedback from increases in lightning NO_x in a warming world (Thornhill et al., 2021a). All AerChemMIP models use a cloud-top height lightning parameterization that predicts increases in lightning with warming. However, a positive climate-lightning NO_x feedback cannot be ruled out because of the dependence of the response to lightning parameterizations as discussed in section 6.2.2.1.

Climate-CH_4 Lifetime feedback: Warmer and wetter climate will lead to increases in OH and oxidation rates leading to reduced atmospheric methane lifetime – a negative feedback (Naik et al., 2013; Voulgarakis et al., 2013). Furthermore, since OH is in turn removed by methane, the climate-methane lifetime feedback will be amplified (Prather, 1996) (also see section 6.3.1). Based on the multimodel results of Voulgarakis et al. (2013), α for climate-methane lifetime is estimated to be -0.030 ± 0.01 W m^{-2} °C^{-1} by Heinze et al., (2019). The assessed central value of α based on the AerChemMIP ensemble is within the range of this estimate but with greater uncertainty (Thornhill et al., 2021a).

Climate-Fire feedback: Wildfires are a major source of SLCF emissions (section 6.2.2.6). Climate change has the potential to enhance fire activity (see Sections 5.4.3.2, Chapter 12.4) thereby enhancing SLCF emissions leading to feedbacks. Climate driven increases in fire could potentially lead to offsetting feedback from increased ozone and decreased methane lifetime (due to increases in OH) leaving the feedback from aerosols to dominate with an uncertain net effect (e.g., Landry et al., 2015). AR5 assessment of climate-fire feedbacks included a value of α due to fire aerosols to be in the range of -0.03 to + 0.06 W m^{-2} °C^{-1} based on Arneth et al. (2010). A recent study estimates climate feedback due to fire aerosols to be greater than that due to BVOCs, with a value of α equal to -0.15 (-0.24 to -0.05) W m^{-2} °C^{-1} (Scott et al., 2018). Clearly, the assessment of fire related non-CO_2 biogeochemical feedbacks is very uncertain because of limitations in the process understanding of the interactions between climate, vegetation and fire dynamics, and atmospheric chemistry and their representation in the current generation ESMs. Some AerChemMIP ESMs include the representation of fire dynamics but do not activate their interaction with atmospheric chemistry. Given the large uncertainty and lack of information from AerChemMIP ESMs, we do not include a quantitative assessment of climate-fire feedback for AR6.

In summary, climate-driven changes in emissions, atmospheric abundances or lifetimes of SLCFs are

ACCEPTED VERSION SUBJECT TO FINAL EDITING

assessed to have an overall cooling effect, i.e., a negative feedback parameter of -0.20 W m^{-2} °C^{-1} with a 5-95% range of -0.41 to + 0.01 W m^{-2} °C^{-1}, thereby reducing climate sensitivity (see Section 7.4.2.5.1). This net feedback parameter is obtained by summing the assessed estimates for the individual feedback given in Table 6.8. *Confidence* in the magnitude and the sign of most of the individual as well as the total non-CO_2 biogeochemical feedbacks remains *low* as evident from the large range in the value of α. This large uncertainty is attributed to the diversity in model representation of the relevant chemical and biogeochemical processes based on limited process-level understanding.

[START TABLE 6.8 HERE]

Table 6.8: Assessed central estimates and the *very likely* ranges (5-95%) of non-CO_2 biogeochemical feedback parameter (α_x) based on the AerChemMIP ensemble estimates (Thornhill et al., 2021a). As in Section 7.4.1.1, α_x (W m^{-2} °C^{-1}) for a feedback variable x is defined as $\alpha_x = \frac{\partial N}{\partial x}\frac{dx}{dT}$ where $\frac{\partial N}{\partial x}$ is the change in TOA energy balance in response to a change in x induced by a change in surface temperature (T). The 5-95% range is calculated as mean ± standard deviation * 1.645 for each feedback. The level of confidence in these estimates is *low* owing to the large model spread. Published estimates of α are also shown for comparison.

6.4.6 ERF by aerosols in proposed Solar Radiation Modification

Solar radiation modification (SRM, see also Sections 4.6.3.3, 8.6.3) have the potential to exert a significant ERF on the climate, mainly by affecting the SW component of the radiation budget (e.g. Caldeira et al., 2013; Lawrence et al., 2018; National Academy of Sciences, 2015). The possible ways and the extent to

ACCEPTED VERSION SUBJECT TO FINAL EDITING

which the most commonly discussed options may affect radiative forcing is addressed in this section. Side-effects of SRM on stratospheric ozone and changes in atmospheric transport due to radiative heating of the lower stratosphere are discussed in Section 4.6.3.3.

Stratospheric aerosol injections have the potential to achieve a high negative global ERF, with maximum ERFs ranging from -2 to -5 W m^{-2} (Niemeier and Timmreck, 2015; Weisenstein et al., 2015; Niemeier and Schmidt, 2017; Kleinschmitt et al., 2018). The magnitude of the maximum achievable ERF depends on the chosen aerosol type and mixture, internal structure and size, or precursor gas (e.g. SO_2), as well as the injection strategy; latitude, altitude, magnitude, and season of injections, plume dispersal, model representation of aerosol microphysics, and ambient aerosol concentrations (Rasch et al., 2008; Robock et al., 2008; Pierce et al., 2010; Weisenstein et al., 2015; Laakso et al., 2017; Macmartin et al., 2017; Dai et al., 2018; Kleinschmitt et al., 2018; Vattioni et al., 2019; Visioni et al., 2019). For sulphur, the radiative forcing efficiency is of around -0.1 to -0.4 W m^{-2} / (TgS yr^{-1}) (Niemeier and Timmreck, 2015; Weisenstein et al., 2015; Niemeier and Schmidt, 2017). Different manufactured aerosols, such as ZrO_2, TiO_2, and Al_2O_3, have different ERF efficiencies compared to sulphate (Ferraro et al., 2011; Weisenstein et al., 2015; Dykema et al., 2016; Jones et al., 2016). The aerosol size distribution influences the optical properties of an aerosol layer, and hence the ERF efficiency, which also depends on the dispersion, transport, and residence time of the aerosols.

For marine cloud brightening (MCB), seeded aerosols may affect both cloud microphysical and macrophysical properties (see also Section 7.3.3.2). By principle, MCB relies on ERF_{aci} through the so-called Twomey effect (Twomey, 1977), but ERF_{ari} may be of equal magnitude as shown in studies that consider spraying of sea salt outside tropical marine cloud areas (Jones and Haywood, 2012; Partanen et al., 2012; Alterskjær and Kristjánsson, 2013; Ahlm et al., 2017). The maximum negative ERF estimated from modelling is within the range of -0.8 to -5.4 W m^{-2} (Latham et al., 2008; Rasch et al., 2009; Jones et al., 2011; Partanen et al., 2012; Alterskjær and Kristjánsson, 2013). For dry sea salt, the ERF efficiency is estimated to be within the range of -3 to -10 W m^{-2} / (Pg yr^{-1}), when emitted over tropical oceans in ESMs in the Geoengineering Intercomparison Project (GeoMIP) (Ahlm et al., 2017). Cloud resolving models reveal complex behaviour and response of stratocumulus clouds to seeding, in that the ERF efficiency depends on meteorological conditions, and the ambient aerosol composition, where lower background particle concentrations may increase the ERF_{aci} efficiency (Wang et al., 2011). Seeding could suppress precipitation formation and drizzle, and hence increase the lifetime of clouds, preserving their cooling effect (Ferek et al., 2000). In contrast, cloud lifetime could be decreased by making the smaller droplets more susceptible to evaporation. Modelling studies have shown that a positive ERF_{aci} (warming) could also result from seeding clouds with too large aerosols (Pringle et al., 2012; Alterskjær and Kristjánsson, 2013). These processes, and the combination of these, are not well understood, and may have a limited representation in models, or counteracting errors (Mülmenstädt and Feingold, 2018), lending *low to medium confidence* to the ERF estimates.

Modelled ERF_{aci} associated with cirrus cloud thinning (CCT) cover a wide range in the literature, and the maximum are of the order of -0.8 to -3.5 W m^{-2}, though they are of *low confidence*, with some studies using more simplified representations (Mitchell and Finnegan, 2009; Storelvmo et al., 2013; Kristjánsson et al., 2015; Jackson et al., 2016; Muri et al., 2018; Gasparini et al., 2020). ERF_{aci} for CCT is mainly affected by particle seeding concentrations, with an optimum around 20 L^{-1}, according to limited evidence from models (Storelvmo et al., 2013). Seeding leading to higher particle concentrations could lead to a warming (Storelvmo et al., 2013; Penner et al., 2015; Gasparini and Lohmann, 2016). The lack of representation of processes related to, for example, heterogeneous and homogeneous freezing and their prevalence, is a dominant source of uncertainty in ERF estimates, in addition to less research activity.

In summary, the aerosol and cloud microphysics involved with SRM are not well understood, with a varying degree of lack of representation of relevant processes in models. ERF of up to several W m^{-2} is reported in the literature, with SAI at the higher end and CCT with lower potentials, though it remains a challenge to establish ERF potentials and efficacies with confidence. Modelling studies have been published with more sophisticated treatment of SRM since AR5, but the uncertainties, such as cloud-aerosol radiation interactions, remain large (*high confidence*).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

6.5 Implications of changing climate on AQ

Air pollutants can be impacted by climate change through physical changes affecting meterorological conditions, chemical changes affecting their lifetimes, and biological changes affecting their natural emissions (Kirtman et al., 2013). Changes in meteorology affect air quality directly through modifications of atmospheric transport patterns (e.g., occurrence and length of atmospheric blocking episodes, ventilation of the polluted boundary layer), extent of mixing layer and stratosphere-troposphere exchange (STE) for surface ozone (Von Schneidemesser et al., 2015), and through modifications of the rate of reactions that generate secondary species in the atmosphere. Changing precipitation patterns in a future climate also influence the wet removal efficiency, in particular for atmospheric aerosols (Hou et al., 2018). Processes at play in non-CO_2 biogeochemical feedbacks (Section 6.4.5) are also involved in the perturbation of atmospheric pollutants (see Section 6.2.2).

This section relies on observational studies performed by analysing correlation between specific meteorological conditions projected to occur more frequently in the future and surface pollutants, and global and regional scale modelling studies considering solely climate change in the future. We also assess the surface ozone and $PM_{2.5}$ changes based on CMIP6 models analysed in AerChemMIP, considering climate change in isolation with emissions in 2050 from SSP3-7.0 scenario (see Section 6.7.1). Air quality being highly variable in space and time, the use of regional atmospheric chemistry models is necessary to characterise the effect of future climate on air quality properly. However, difficulties for such assessment arise from the need for long simulations that include complex chemistry-natural system interactions with high computational cost, in addition to the difficulty related to the regionalisation of climate change (see Section 10.3.1.2). Changes in the occurrence of weather patterns influencing air pollution (e.g., anticyclonic stagnation conditions, transport pathways from pollution sources, convection) due to climate change are assessed in Chapters 4 and 11.

6.5.1 Effect of climate change on surface O_3

AR5 assessed with high confidence that (Kirtman et al., 2013), in unpolluted regions, higher water vapour abundances and temperatures in a warmer climate would enhance ozone chemical destruction, leading to lower baseline[5] surface ozone levels. In polluted regions, AR5 assessed with medium confidence that higher surface temperatures will trigger regional feedbacks in chemistry and local emissions that will increase surface ozone and intensity of surface O_3 peaks.

The response of surface ozone to climate induced Earth system changes is complex due to counteracting effects. Studies considering the individual effects of climate driven changes in specific precursor emissions or processes show increases in surface ozone under warmer atmosphere for some processes. This is indeed the case for enhanced STE and stratospheric ozone recovery (Sekiya and Sudo, 2014; Banerjee et al., 2015; Hess et al., 2015; Meul et al., 2018; Morgenstern et al., 2018; Akritidis et al., 2019) or the increase of soil NO_x emissions (Wu et al., 2008; Romer et al., 2018), which can each lead to 1 to 2 ppb increase in surface ozone. Other processes, in particular deposition or those related to emissions from natural systems (see section 6.2.2) are expected to play a key role in future surface ozone and even occurrence of pollution events (e.g. in the case of wildfires) but their effects are difficult to quantify in isolation.

Since the AR5, several studies have investigated the net effect of climate change on surface ozone, based on either global or regional model projections. A systematic and quantitative comparison of the ozone change, however, is difficult due to the variety of models with different complexities in the representation of natural emissions, chemical mechanisms, and physical processes as well as the surface O_3 metrics applied for analysis. Processes like temperature-, CO_2-sensitive BVOC emissions, deposition, and branching ratio in isoprene nitrates chemistry have been shown to be particularly sensitive (Squire et al., 2015; Val Martin et al., 2015; Schnell et al., 2016; Pommier et al., 2018). More robust protocol are now used more commonly

[5] Baseline ozone is defined as the observed ozone at a site when it is not influenced by recent, locally emitted or anthropogenically produced pollution (Jaffe et al., 2018).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

comprising, notably, longer simulations necessary to separate change from interannual variability (Lacressonnière et al., 2016; Garcia-Menendez et al., 2017) (Barnes et al., 2016). However, the amplitude of climate change penalty on ozone over polluted regions may be different in high-resolution (regional and urban-scale) models in comparison to coarse resolution global models as a number of controlling processes are resolution-dependent including e.g local emissions, sensitivity to the chemical regime (VOC limited versus NO_x limited) (Lauwaet et al., 2014; Markakis et al., 2014, 2016).

Consistent with AR5 findings, global surface ozone concentration decreases by up to -1.2 to 2.3 ppb for annual mean due to the dominating role of ozone destruction by water vapor are found in four member ensemble of CMIP6 ESM for surface warmings of 1.5 to 2.5 °C (Figure 6.14). This decrease is driven by the ozone decrease over oceans, especially in the tropics (decrease of 1 ppb to 5 ppb) and large parts of the continental unpolluted regions. The sensitivity of annual mean surface ozone to the level of surface warming over these remote areas varies spatially from -0.2 to -2 ppb $^{o}C^{-1}$ (see Figure 6.SM.1 in the Supplementary Material)

Over ozone producing regions of the world, such as in North America, Europe, and East Asia, AR5 and post AR5 model studies project a general increase of surface ozone levels (climate change penalty on ozone) in a future warmer climate particularly during summertime (Fu and Tian, 2019). However, in current regional models, using more robust protocols, this increase of surface ozone, attributable to climate change is of lower magnitude than in previous estimates (Lacressonnière et al., 2016; Garcia-Menendez et al., 2017). Climate change enhances the efficiency of precursor emissions to generate surface ozone in polluted regions, (Schnell et al., 2016) and thus the magnitude of this effect will depend on the emissions considered in the study (present or future, and mitigated or not) (Colette et al., 2015; Fiore et al., 2015).

Considering anthropogenic emissions of precursors globally higher than the current emissions (SSP3-7.0 in 2050, see Figure 6.20), the CMIP6 ensemble confirms the surface O_3 penalty due to climate change over regions close to anthropogenic pollution sources or close to natural emission sources of ozone precursors (e.g. biomass burning areas), with a penalty of a few ppb for the annual mean, proportional to warming levels (Figure 6.14). This rate ranges regionally from 0.2 to 2 ppb $^{o}C^{-1}$ (see Figure 6.SM.1 in Supplementary Material). The CMIP6 ESMs show this consistently for South East Asia (in line with Hong et al., (2019) and Schnell et al. (2016)) and for India (in line with (Pommier et al., 2018) as well as in parts of Africa and South America, close to enhanced BVOC emissions (at least 3 out 4 ESMs agree on the sign of change). The results are mixed in polluted regions of Europe and US because of lower anthropogenic precursor emissions which leads to a very low sensitivity of surface ozone to climate change (-0.5 ppb $°C^{-1}$ to 0.5 ppb $°C^{-1}$) (see Figure 6.SM.1 in Supplementary Material) and thus the ESMs can disagree on sign of changes for a given warming level. This heterogeneity in the results is also found in regional studies over North America (Gonzalez-Abraham et al., 2015; Val Martin et al., 2015; Schnell et al., 2016; He et al., 2018; Nolte et al., 2018; Rieder et al., 2018) or over Europe (Colette et al., 2015; Lacressonnière et al., 2016; Schnell et al., 2016; Fortems-Cheiney et al., 2017).

Overall, warmer climate is expected to reduce surface ozone in unpolluted regions as a result of greater water vapor abundance accelerating ozone chemical loss (*high confidence*). Over regions with high anthropogenic and/or natural ozone precursor emissions, there is prevailing evidence that climate change will introduce a surface O_3 penalty increasing with increasing warming levels (with a magnitude ranging regionally from 0.2 to 2 ppb $°C^{-1}$) (*medium confidence to high confidence*). Yet, there are uncertainties in processes affected in a warmer climate which can impact and modify future baseline and regional/local surface ozone levels. The response of surface ozone to future climate change through stratosphere-troposphere exchange, soil NO_x emissions and wildfires is positive (*medium confidence)*. In addition, there is *low confidence* in the magnitude of effect of climate change on surface ozone through biosphere interactions (natural CH_4, non-methane BVOC emissions and ozone deposition) and lighting NO_x emissions.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

[START FIGURE 6.14 HERE]

Figure 6.14: Multi-model annual mean change in surface ozone (O_3) (ppb) concentrations at different warming levels. Changes are shown for a) 1.0°C, b) 1.5°C, c) 2.0°C and d) 2.5°C increase in global mean surface air temperature. CMIP6 models include GFDL-ESM4, GISS-E2-1-G, MRI-ESM2-0 and UKESM1-0-LL. For each model the change in surface O3 is calculated as difference between the ssp370SST and ssp370pdSST experiments in the year when the difference in the global mean surface air temperature between the experiments exceeds the temperature threshold. The difference is calculated as a 20-year mean in surface O_3 around the year when the temperature threshold in each model is exceeded. The multi-model change in global annual mean surface O_3 concentrations with ± 1 σ are shown within parenthesis. Uncertainty is represented using the simple approach: No overlay indicates regions with high model agreement, 3 out of 4 models agree on sign of change; diagonal lines indicate regions with low model agreement, where 3 out of 4 models agree on sign of change. For more information on the simple approach, please refer to the Cross-Chapter Box Atlas.1. Further details on data sources and processing are available in the chapter data table (Table 6.SM.1).

[END FIGURE 6.14 HERE]

6.5.2 Impact of climate change on particulate matter

Changes in concentration and chemistry of particulate matter (PM) in a changing climate depend in a complex manner on the response of the multiple interactions of changes in emissions, chemical processes, deposition and other factors (e.g., temperature, precipitation, circulation patterns). These changes are difficult to assess and, at the time of AR5, *no confidence level* was attached to the overall impact of climate change on $PM_{2.5}$ (Kirtman et al., 2013). Possible changes induced by climate change may concern both atmospheric concentration levels and chemical composition.

Higher temperatures increase the reaction rate of gaseous SO_2 to particulate sulphate conversion but also favour evaporation of particulate ammonium nitrate (Megaritis et al., 2013). Also, higher temperatures are expected to affect BVOC emissions (e.g. Pacifico et al., 2012) that would influence SOA concentrations, although this effect has been questioned by more recent evidence (Wang et al., 2018a; Zhao et al., 2019c). More generally, climate change will also affect dust concentration levels in the atmosphere (see Section 6.2.2.4) and the occurrence of forest fires, both very large sources of aerosols to the global troposphere (see Section 6.2.1.2.3).

Wet deposition constitutes the main sink for atmospheric PM (Allen et al., 2016b, 2019b; Xu and Lamarque, 2018). In particular, precipitation frequency has a higher effect on PM wet deposition than precipitation intensity (Hou et al., 2018). PM is also sensitive to wind speed and atmospheric stability conditions emphasising the importance of stagnation episodes and low planetary boundary layer heights for increasing PM atmospheric concentrations (Porter et al., 2015).

At the global scale, depending on its magnitude, the warming leads either to a small increase in global mean PM concentration levels (ca. 0.21 μg m^{-3} in 2100 for RCP8.5), mainly controlled by sulphate and organic aerosols or a small decrease (-0.06 μg m^{-3} for RCP2.6), Westervelt et al. (2016) and Xu and Lamarque (2018). On the other hand, Xu and Lamarque (2018) and Allen et al. (2016c, 2019b) found an increase of aerosol burden and PM surface concentration throughout the 21st Century, attributed to a decrease in wet removal flux despite the overall projected increase in global precipitation, on the ground of an expected shift of future precipitation towards more frequent heavy events. Based only on three models, the CMIP6 ensemble shows that for most land areas, there is low agreement between models on the sign of climate change on annual mean $PM_{2.5}$ (see Figure 6.SM.2 in Supplementary Material).

Due to the typical atmospheric lifetime of PM in the atmosphere, of the order of a few days, most studies dealing with the future PM concentration levels have a regional character and concern mainly Europe (Megaritis et al., 2013; Lacressonnière et al., 2016, 2017; Lemaire et al., 2016; Cholakian et al., 2019), the US (Penrod et al., 2014; Fiore et al., 2015; Gonzalez-Abraham et al., 2015; Shen et al., 2017; He et al., 2018;

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Nolte et al., 2018), South and East Asia (Jiang et al., 2013; Nguyen et al., 2019) and India (Pommier et al., 2018). No studies are available for other areas of the world.

Changes in the chemical composition of PM as a result of future climate change can also be an important issue for the effects of PM on human health and the environment, but only a few sparse data are available in the literature on this and the results are, as yet, inconclusive (Im et al., 2012; Jiang et al., 2013; Megaritis et al., 2013; Gonzalez-Abraham et al., 2015; Gao et al., 2018; He et al., 2018; Cholakian et al., 2019).

Overall, there is *medium confidence* (*medium evidence, high agreement*) in a small effect, positive or negative, on PM global burden due to climate change.

6.5.3 Impact of climate change on extreme pollution

Extreme air pollution is identified as the concentration of an air pollutant that is above a given threshhold value (high concentration or a high percentile) as the sensitivity of peak values to meteorological conditions can be different from sensitivity of the median or mean (Porter et al., 2015). AR5 assessed with medium confidence that uniformly higher temperatures in polluted environments will trigger regional feedbacks in chemistry and local emissions that will increase peak ozone and PM pollution, but assessed low confidence in projecting changes in meteorological blocking associated with these extreme episodes.

Meteorological conditions, such as heat waves, temperature inversions, and atmospheric stagnation episodes favor air quality extremes and are influenced by changing climate (Fiore et al., 2015). The body of literature on the connection between climate change and extreme anthropogenic pollution episodes is essentially based on correlation and regression applied to observation reanalysis but the metrics and methodologies differ making quantitative comparisons difficult. Many emission processes in the natural systems are sensitive to temperature, and burst of emissions as a reponse to extreme weather, as in the case of wildfires in dry conditions (Bondur et al., 2020; Xie et al., 2020) can occur which would then add to the risk of extreme air pollution but are not sufficiently constrained to be quantitatively assessed.

Since AR5, published studies provide augmented evidence for the connections between extreme ozone and PM pollution events and high temperatures, especially long-lasting heat waves, whose frequency is increasing due to a warming climate (Lelieveld et al., 2014; Porter et al., 2015; Hou and Wu, 2016; Schnell and Prather, 2017; Zhang et al., 2017b) (Sun et al., 2017) Jing et al., 2017. However, relationship between air pollution and individual meteorological parameters is exaggerated because of covariation on synoptic time scales (Fiore et al., 2015). For example, heatwaves are often associated with clear-skies and stagnation, making clear attribution to specific meteorological variable complicated. In Asia, future changes in winter conditions have also been shown to favour more particulate pollution (Cai et al., 2017), and (Zou et al. (2017). The relationship between the occurrence of stagnation episodes and high concentrations of ozone and $PM_{2.5}$ has been shown to be regionally and metric dependant (Oswald et al., 2015; Sun et al., 2017; Kerr and Waugh, 2018; Schnell et al., 2018; Garrido-Perez et al., 2019).

The increase of heatwaves frequency, duration and intensity is extremely likely on all continents for different future warming levels (Chapter 11, see Table 11.2 and Section 11.3.5). However, there is low confidence in projected changes in storm tracks, jets, and blocking and thus their influence in extreme temperatures in mid-latitudes (See Section 11.3.1).

In conclusion, there is still *medium confidence* that climate driven changes in meterorological conditions, such as heatwaves or stagnations, will favour extreme air pollution episodes over highly polluted areas, however the relationship between these meteorological conditions and high concentrations of ozone and $PM_{2.5}$ have been shown to be regionally and metric dependant.

6.6 Air Quality and Climate response to SLCF mitigation

LLGHG emission reductions are typically motivated by climate mitigation policies, whereas SLCF reductions mostly result from air pollution control, climate policies (see FAQ6.2) as well as policies focusing on achieving UN Sustainable Development Goals (SDGs) (see Box 6.2). The management of several SLCFs (BC, CH_4, tropospheric O_3, and HFCs) is considered in the literature as a fast-response, near-term measure to curb climate change, while reduction of emissions of LLGHGs is an essential measure for mitigating long-term climate warming (Shindell et al., 2012a, 2017a; Shoemaker et al., 2013; Rogelj et al., 2014b; Lelieveld et al., 2019). Note that the term short-lived climate pollutants (SLCPs) refering only to warming SLCFs has been used within the policy arena. The SR 1.5 report states that limiting warming to 1.5°C to achieve Paris Agreement goals, implies net zero CO_2 emissions around 2050 and concurrent deep reductions in emissions of non-CO_2 forcers, particularly methane (Rogelj et al., 2018a). In addition, several SLCFs are key air pollutants or precursors of fine particulate matter (PM2.5) and tropospheric O3 and therefore subject to control driven by air quality targets.

Policies addressing either SLCFs or LLGHGs reduction, often prioritize mitigation of specific anthropogenic sources, such as energy production, industry, transportation, agriculture, waste management, and residential fuel use. Choice of the targetted sector and chosen measures will determine the ratios of emitted SLCFs and LLGHGs. These changes in emissions of co-emitted species will result in diverse responses driven by complex chemical and physical processes and resulting climate perturbations (see Section 6.5). The understanding of the co-benefits through sectoral mitigation efforts (as well as potential negative impacts) is essential to inform policy making.

The discussion of targeted SLCF policies and their role in climate change mitigation ranges from critical evaluation of the climate co-benefits (Smith and Mizrahi, 2013; Pierrehumbert, 2014; Rogelj et al., 2014b; Strefler et al., 2014; Allen et al., 2016a), modelling the potential of dedicated BC and CH_4 reductions in association with or without climate policy (Harmsen et al., 2019; Smith et al., 2020), individual or multi-component mitigation in relation to natural variability (Samset et al., 2020), warning about the risk of diversion of resources from LLGHGs, especially CO_2, policies (e.g., Shoemaker et al., 2013), to seeing it as an opportunity to strengthen commitment and accelerate action on LLGHGs (Victor et al., 2015; Aakre et al., 2018).

Over the last decade, research on air quality-climate interactions and feedbacks has brought new attention of policy communities on the possibility of win-win mitigation policies that could both improve air quality and mitigate climate change, possibly also reducing the cost of interventions (Anenberg et al., 2012; Shindell et al., 2012a, 2017a, Schmale et al., 2014a, 2014b; Sadiq et al., 2017; Fay et al., 2018; Harmsen et al., 2020). Haines et al. (2017a) and Shindell et al. (2017a) connect the measures to mitigate SLCFs with the achievements of some of the SDGs. Indeed, most studies on co-benefits to date focus on the impacts of climate mitigation strategies, in particular to meet Nationally Determined Contributions (NDCs) and/or specific global temperature targets, on air quality and human health (West et al., 2013; Zhang et al., 2016; Rao et al., 2016; Shindell et al., 2016, 2017a; Chang et al., 2017; Haines et al., 2017a; Xie et al., 2018; Li et al., 2018a; Markandya et al., 2018; Williams et al., 2018; Lelieveld et al., 2019). Such co-benefits of climate mitigation for air quality and human health can offset the costs of the climate measures (Saari et al., 2015; Li et al., 2018a). A growing number of studies analyse the co-benefits of current and planned air quality policies on LLGHGs and global and regional climate change impacts (Lund et al., 2014a; Akimoto et al., 2015; Lee et al., 2016; Maione et al., 2016; Peng et al., 2017).

This section assesses the effects of mitigating SLCFs, motivated by various objectives, discussing temperature response time, temperature and air quality attribution of SLCFs sources, and chosen mitigation approach. The effects of the measures, to contain the spread of COVID-19 in 2020, on air quality (AQ) and climate are discussed in cross-chapter Box 6.1 at the end of this section.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

6.6.1 Implications of lifetime on temperature response time horizon

The effect over time on GSAT following a mitigation effort affecting emissions of LLGHGs or SLCFs depends on the lifetimes of the LLGHGs and SLCFs, their radiative efficiencies, how fast the emissions are reduced, how long reductions last (limited time or sustained reduction), and the inertia of the climate system itself. Mitigation of SLCFs are often implemented through new legislation or technology standards for the different emission sectors and components, implying that reductions are sustained over time.

It is often perceived that the full climatic response following mitigation of SLCFs will occur almost immediately. However the inertia of the climate system strongly modifies the short-term and long-term response. SLCFs with lifetimes shorter than the time scales for interhemisheric mixing (1-2 years) can cause a more spatially heterogeneous forcing than LLGHGs and thus different regional patterns of the climate response (see Sections 6.4.3). The temporal response in GSAT to a radiative forcing can be quantified using linear impulse response functions (see Cross Chapter box 7.1), (Olivié and Peters, 2013; Geoffroy et al., 2013; Smith et al., 2018). Figure 6.15 shows the GSAT response for sustained step reduction in emissions of idealised SLCFs with different lifetimes. The response is relative to a baseline with constant emissions, so effects of emissions before the step reduction is not shown. For SLCFs with lifetimes shorter than a few years, the concentrations quickly reach a new steady state and the response time is primarily governed by the thermal inertia and thus the time scales of the climate system. For compounds with lifetime on the order of 10 years (for example methane), there is about a 10-year delay in the response during the first decades, compared to compounds with lifetimes less than one year. However on longer time scales the response is determined solely by the time scales of the climate system itself. For CO_2 (dashed line in Figure 6.15) the temporal response is very different due to the long time scale for mixing into the deep ocean and therefore a substantial fraction of atmospheric CO_2 is only removed on millenium time scales. This means that for SLCFs including methane, the rate of emissions drives the long term stabilisation, as opposed to CO_2 where the long term effect is controlled by cumulative emissions (Allen et al., 2018b). Methods to compare rates of SLCF emission with cumulative CO_2 emissions are discussed in chapter 7, section 7.6.1.4.

[START FIGURE 6.15 HERE]

Figure 6.15: Global mean surface air temperature (GSAT) response to an abrupt reduction in emissions (at time t=0) of idealized climate forcing agents with different lifetimes. All emissions are cut to give a radiative forcing of -1 W m^{-2} at steady state (except for CO_2). In other words, if the yearly emissions are E0 before the reduction, they will have a fixed lower value $E_{year>0}$ = (E0 - ΔE) for all succeeding years. For comparison, the GSAT response to a sustained reduction in CO_2 emissions resulting in an RF of -1 W m^{-2} in year 100 is included (dashed line). The temperature response is calculated using an impulse response function (see Cross-Chapter Box 7.1) with a climate feedback parameter of -1.31 W m^{-2} °C^{-1}. Further details on data sources and processing are available in the chapter data table (Table 6.SM.1).

[END FIGURE 6.15 HERE]

As a consequence, in idealized ESM studies that assume an instantaneous removal of all anthropogenic or fossil fuel-related emissions, a rapid change in aerosol levels occurs leading to large increases in GSAT with the rate of warming lasting for several years. Similarly, the thermal inertia causes the pulse emissions (Figure 6.16) of SLCFs to have a significant effect on surface temperature even after 10 years.

In summary, for SLCFs with short lifetime (e.g. months), the response in surface temperature occurs strongly as soon as a sustained change in emissions is implemented and continues to grow for a few years, primarily due to thermal inertia in the climate system (*high confidence*). Near its maximum, the response slows down but will then take centuries to reach equilibrium (*high confidence*). For SLCF with longer lifetimes (e.g. a decade), a delay equivalent to their lifetimes comes in addition to the delay due the thermal inertia (*high confidence*).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

6.6.2 Attribution of temperature and air pollution changes to emission sectors and regions

Assessment of the temperature response to source emission sectors is important for identifying priority mitigation measures and designing efficient mitigation strategies.

Temperature effects of emissions can be quantified for the historical contribution to the present temperature impact (see 6.4.2), for idealized one-year pulses of emissions or for continued (sustained) emissions at present levels and for changes during a specific time period, for emissions from future scenarios with various hypotheses, giving complementary information to feed mitigation strategies. AR5 assessed the net global temperature impact of source emission sectors from a one-year pulse (single year worth) of year 2008 emissions and found that the largest contributors to warming on 50-100 year time scales are the energy, industrial and on-road transportation sectors. Sectors that emit large amounts of methane (agriculture and waste management) and black carbon (residential biofuel) are important contributors to warming over short time horizons up to 20 years. Below, we discuss the effect on ERFs, temperature and air pollution of selected key sectors estimated to have large non-CO_2 forcing, including agriculture, residential and commercial, and transport (aviation, shipping, land transportation).

6.6.2.1 Agriculture

According to the SRCCL assessment (Jia et al., 2019), agriculture, forestry and other land use (AFOLU) is a significant net source of GHG emissions (*high confidence*), with more than half of these emissions attributed to non-CO_2 GHGs from agriculture. With respect to SLCFs, agricultural activities are major global sources of CH_4 and NH_3 (Section 6.2.1). The agriculture sector exerts strong near term warming due to large CH_4 emission that is slightly offset by a small cooling from secondary inorganic aerosols formed notably from the NH_3 emission (Heald and Geddes, 2016b; Lund et al., 2020). For present day emissions, agriculture is the 2nd largest contributor to warming on short time scales but with a small persisting effect on surface temperature (+0.0012±0.00028°C) after a pulse of current emissions (Lund et al., 2020 and Figure 6.16, see detailed description in 6.6.2.3.4). Aerosols produced from agricultural emissions, released after nitrogen fertilizer application and from animal husbandry, influence surface air quality and make an important contribution to surface $PM_{2.5}$ in many densely populated areas (Lelieveld et al., 2015b; Bauer et al., 2016) and Figure 6.17.

6.6.2.2 Residential and Commercial cooking, heating

The residential and commercial sector is associated with SLCF emissions of carbonaceous aerosol, CO and VOCs, SO_2 and NO_x and can be split by fuel type (biofuel or fossil fuel) where residential fossil fuel is also associated with CO_2 and CH_4 emissions (Section 6.2.1). The impacts of residential CO and VOC emissions are warming and SO_2 and NO_x are net cooling. However, the net sign of the global radiative effects of carbonaceous aerosols from the residential sector and solid fuel cookstove emissions (warming or cooling) is not well constrained based on evidence from recent global atmospheric modelling studies. Estimates of global residential sector direct aerosol-radiation effects range from -20 to +60 mW m^{-2} (Kodros et al., 2015) and -66 to +21 mW m^{-2} (Butt et al., 2016); and aerosol-cloud effects range from -20 to +10 mWm^{-2} (Kodros et al., 2015) and -52 to -16 mW m^{-2} (Butt et al., 2016). Uncertainties are due to assumptions about the aerosol emission masses, size distribution, aerosol optical properties and mixing states (see Section 6.3.5.3). Allowing BC to act as an INP in a global model leads to a much larger global forcing estimate from -275 to +154 mW m^{-2} with large uncertainty range due to uncertainty in the plausible range of maximum freezing efficiency of BC (Huang et al., 2018). The net sign of the impacts of carbonaceous aerosols from residential burning on radiative forcing and climate (warming or cooling) is ambiguous. The residential biofuel sector is a major concern for indoor air quality (Bonjour et al., 2013). In addition, several atmospheric modelling studies find that this sector is also important for outdoor air quality and even a dominant source of population-weighted outdoor $PM_{2.5}$ in India and China (Lelieveld et al., 2015b; Silva et al., 2016a; Spracklen et al., 2018, Figure 6.17; Reddington et al., 2019).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

The net climate impact of the residential sector is warming in the near term of +0.0018±0.00084°C for fossil fuel use and +0.0014±0.0012°C for biofuel use, and +0.0017±0.00017°C and +0.0001±0.000079°C, respectively over a 100 years horizon, after a one year pulse of current emissions (Lund et al., 2020), due to the effects of BC, CH_4, CO and VOCs which adds to that of CO_2 but the uncertainty in the net sign of carbonaceous aerosol impacts challenges overall quantitative understanding of this sector and leads to *low confidence* in this assessment. Residential sector emissions are an important source of indoor and outdoor air pollution in Asia and globally (*high confidence*).

6.6.2.3 Transportation

6.6.2.3.1 Aviation

Aviation is associated with a range of SLCFs from emissions of NO_x, aerosol particles, and NO_x, alongside its emissions of water vapour and CO_2. The largest SLCF effects are those from the formation of persistent condensation trails (contrails) and NO_x emissions. Persistent contrails are ice crystal clouds, formed around aircraft soot particles (and water vapour from the engine), when the ambient cold and ice-supersaturated atmosphere, which can spread and form contrail cirrus clouds. The 'net NO_x' effect arises from the formation of tropospheric O_3, counterbalanced by the destruction of ambient CH_4 and associated cooling effects of reductions in stratospheric water vapour and background O_3. AR5 assessed the radiative forcing from persistent linear contrails to be +0.01 (+0.005 to +0.03) W m^{-2} for year 2011, with a medium confidence (Boucher et al., 2013). The combined linear contrail and their subsequent evolution to contrail cirrus radiative forcing from aviation was assessed to be +0.05 (+0.02 to +0.15) W m^{-2}, with a low confidence. An additional forcing of +0.003 W m^{-2} due to emissions of water vapour in the stratosphere by aviation was also reported (Boucher et al., 2013). The aviation sector was also estimated to lead to a net surface warming at 20 and 100 years horizons following a one year pulse emission. This net temperature response was determined by similar contributions from contrails and contrail cirrus and CO_2 over a 20 year time horizon, and dominated by CO_2 in a 100 years perspective (Figure 8.34 AR5: Myhre et al., 2013).

Our assessment builds on Lee et al. (2020a). Their study consists of an updated, comprehensive assessment of aviation climate forcing in terms of RF and ERF based on a large number of studies and the most recent air traffic and fuel use datasets available (for 2018), new calculations and the normalization of values from published modeling studies, and combining the resulting best estimates via a Monte-Carlo analysis. Lee et al. (2020a), reports a net aviation ERF for year 2018 emissions of +0.101 W m^{-2} (5–95% likelihood range of 0.055–0.145) with major contributions from contrail cirrus (0.057 W m^{-2}), CO_2 (0.034 W m^{-2}), and NO_x (0.017 W m^{-2}). Contrails and aviation-induced cirrus yields the largest individual positive ERF term, whose confidence level is similarly assessed to Lee et al. (2020a), as 'low' by Chapter 7 (Section 7.3.4.2) due to potential missing processes, followed by CO_2 and NO_x emissions (Lee et al., 2020a). The formation and emission of sulphate aerosol yields a negative (cooling) term. SLCF forcing terms contribute about 8 times more than CO_2 to the uncertainty in the aviation net ERF in 2018 (Lee et al., 2020a). The largest uncertainty in assessing aviation climate effects is on the interactions of BC and sulphate aerosols on cirrus and mixed phase clouds, for which no best estimates of the ERFs were provided (Lee et al., 2020a).

One of the most significant changes between AR5 and AR6 in terms of aviation SLCFs is the explicit calculation of a contrail cirrus ERF found to be 35% of the corresponding RF Bickel et al. (2020), which has confirmed studies indicating smaller efficacy of linear contrails Ponater et al. (2005) and Rap et al. (2010). The net-NO_x term is generally agreed to be a positive RF in the present day, although attribution in a non-linear chemical system is problematic (Grewe et al., 2019) but Skowron et al. (2021) point out that the sign of net NO_x term is dependent on background conditions and could be negative under certain future scenarios.

The best estimate ERFs from aviation (Lee et al., 2020b) have been used to calculate aviation-specific Absolute Global Temperature change Potential (AGTP) using the method described in (Lund et al., 2020) and subsequently compute the effect of one-year pulse of aviation emissions on global-mean surface temperature on a 10- and 100-year time horizon (Figure 6.16, see 6.6.2.3.4). The effect of contrail-cirrus is most important for the estimated net GSAT response after the first decade, followed by similar warming contributions from NO_x and CO_2 emissions. At a 20-year time horizon, the net contribution from aviation to

ACCEPTED VERSION SUBJECT TO FINAL EDITING

GSAT has switched from positive to a small negative effect (see 6.SM.4). This is due to the combination of rapidly decaying contrail-cirrus warming and the complex time variation of the net temperature response to NO_x emissions, which changes sign between 10 and 20 years due to the balance between the positive short-lived ozone forcing and negative forcing from changes in CH_4 and CH_4-induced changes in ozone and stratospheric water vapour. The net GSAT response to aviation emissions has previously been estimated to be positive on a 20-year time horizon (Chapter 8 AR5; Lund et al., 2017). This difference in net GSAT after 20 years in AR5 compared to AR6 results primarily from a shorter time scale of the climate response in the underlying AGTP calculations in Lund et al. (2020), which means the initial, strong impacts of the most short-lived SLFCs, including the warming by contrail-cirrus decay faster, in turn giving the net NO_x effect a relatively higher importance after 20 years. On longer time horizons, the net GSAT response switches back to positive, as CO_2 becomes the dominating warming contribution.

In summary, the net aviation ERF is assessed to be +0.1 W m^{-2} (±0.045) for the year 2018 (*low confidence)*. This confidence level is largely a result of the fact that the SLCF-related terms which counts for more than half (66% of the net aviation ERF) are the most uncertain terms. The climate response to SLCF-related aviation terms exhibits substantial spatiotemporal heterogeneity in characteristics (*high confidence*). Overall, cirrus and contrail cirrus warming, as well as NO_x-induced ozone increase, induce strong, but short-lived warming contributions to the GSAT response ten years after a one-year pulse of present-day aviation emissions (*medium confidence*), while CO_2 both gives a warming effect in the near term and dominates the long-term warming impact (*high-confidence*).

6.6.2.3.2 Shipping

Quantifying the effects of shipping on climate is particularly challenging because (i) the sulphate cooling impact is dominated by aerosol cloud interactions and (ii) ship emissions contain NO_x, SO_x and BC, which lead to mixed particles. Previous estimates of the sulphate radiative effects from present day shipping span the range -47 to -8 mW m^{-2} (direct radiative effect) and -600 to -38 mW m^{-2} (indirect radiative effects) (Balkanski et al., 2010; Eyring et al., 2010; Lauer et al., 2007; Lund et al., 2012). Partanen et al. (2013) reported a global mean ERF for year 2010 shipping aerosol emissions of -390 mW m^{-2}. The temperature change has been shown to be highly sensitive to the choice of aerosol-cloud parameterization (Lund et al., 2012). One year of global present-day shipping emissions, not considering impact of recent low sulphur fuel regulation (IMO, 2016), are estimated to cause net cooling in the near term (-0.0024±0.0025°C) and slight warming (+0.00033±0.00015°C) on a 100-year horizon (Lund et al., 2020).

Shipping is also of importance for air pollution in coastal areas along the major trade routes, especially in Europe and Asia (Corbett et al., 2007; Liu et al., 2016b, Figure 6.17; Jonson et al., 2020). Jonson et al. (2020) estimated that shipping is responsible for 10% or more of the controllable $PM_{2.5}$ concentrations and depositions of oxidised nitrogen and sulphur for many coastal countries. Widespread introduction of low-sulphur fuels in shipping from 2020 (IMO, 2016) will lead to improved air quality and reduction in premature mortality and morbidy (Sofiev et al., 2018).

In summary, one year of present-day global shipping emissions (i.e., without the implementation of the 2020 clean fuel standards) cause a net global cooling (-0.0024±0.0025°C) on 10-20 year time horizons (*high confidence*) but its magnitude is of *low confidence*.

6.6.2.3.3 Land transportation

The on-road and off-road transportation sectors have a net warming impact on climate over all time scales (Berntsen and Fuglestvedt, 2008; Fuglestvedt et al., 2008; Unger et al., 2010; Lund et al., 2020). One year pulse of present day emissions has a small net global temperature effect on short time-scales (+0.0011±0.0045°C), predominantly driven by CO_2 and BC warming offset by NO_x-induced cooling through CH_4 lifetime reductions (Lund et al., 2020).

The vehicle tailpipe emission profiles of diesel and gasoline are distinctly different. Diesel air pollutant emissions are dominated by BC and NO_x whereas petrol air pollutant emissions are dominated by CO and

ACCEPTED VERSION SUBJECT TO FINAL EDITING

NMVOCs, especially when distribution and upstream losses are considered. Thus, net radiative effect of the on-road vehicle fleets depends upon the share of different fuels used, in particular gasoline and diesel (Lund et al., 2014b; Huang et al., 2020b). The net SLCF for year 2010 emissions from the global diesel vehicle fleet have been estimated to be +28 mW m^{-2} (Lund et al., 2014b). Huang et al. (2020b) estimated net global radiative effects of SLCFs (including aerosols, O_3, and CH_4) from the gasoline and diesel vehicle fleets in year 2015 at +13.6 and +9.4 mW m^{-2}, respectively, with similar fractional contributions of SLCFs to the total global climate impact including CO_2 on the 20-year time scale (14-15%).

There is a consensus that on-road transportation sector emissions, including gasoline and diesel, are important anthropogenic contributors to elevated surface O_3 and $PM_{2.5}$ concentrations (Chambliss et al., 2014; Lelieveld et al., 2015b; Silva et al., 2016a, Figure 6.17; Anenberg et al., 2019). At a global-scale, land transportation has been estimated to be the dominant contributor to surface ozone concentrations in populated areas (Silva et al., 2016b) and O_3-induced vegetation damages (Section 6.4.4) (Unger et al., 2020). Furthermore, it is now well established that real world diesel NO_x emission rates are substantially higher, the so-called "excess NO_x", in all regional markets than in laboratory tests worsening air quality (Anenberg et al., 2017; Jonson et al., 2017; Chossière et al., 2018) and contributing to slightly larger warming on the scale of years and smaller warming at the decadal scale (Tanaka et al., 2018). Excess NO_x emissions from key global diesel markets are estimated at 4.6 Tg a^{-1} in 2015, with annual mean O_3 and $PM_{2.5}$ increases of 1 ppb and 1μg m^{-3} across large-regions of Europe, India and China (Anenberg et al., 2017).

In summary, the present-day global land-based transport pulse emissions cause a net global warming on all time scales (*high confidence*) and are detrimental to air quality (*high confidence*).

6.6.2.3.4 GSAT response to emission pulse of current emissions

Figure 6.16 presents the GSAT response to an idealized pulse of year 2014 emissions of individual SLCF and LLGHG. The GSAT response is calculated for 11 sectors and 10 regions accounting for best available knowledge and geographical dependence of the forcing efficacy of different SLCFs (Lund et al., 2020). Two time horizons are shown (10 and 100 year) to represent near- and long-term effects (and 20 year horizon is presented in Figure 6.SM.3). Other time horizon choices may affect the relative importance, and even sign in the case of the NO_x effect, of the temperature response from some of the SLCFs, or be more relevant for certain applications. GSAT response is calculated using the concept of AGTP (see Section 7.6.2.2). Further details of the AGTP emulator applied in Figure 6.16 are provided in (Lund et al., 2020) and 6.SM.4 (see also Section 7.6.1.2, cross-chapter Box 7.1 and 7.SM.7.2). As discussed in Lund et al. (2020), the AGTP framework is primarily designed to study relative importance of individual emissions and sources, but the absolute magnitude of temperature responses should be interpreted with care due to the linearity of the AGTP, which does not necessarily capture all the non-linear effects of SLCFs emissions on temperature.

Differences in the mix of emissions result in net effects on GSAT that vary substantially, in both magnitude and sign, between sectors and regions. SLCFs contribute substantially to the GSAT effects of sectors on short time horizons (10-20 years) but CO_2 dominates on longer time horizons (Figure 6.16). As the effect of the SLCFs decays rapidly over the first few decades after emission, the net long-term temperature effect is predominantly determined by CO_2. N_2O adds a small contribution to the long-term effect of agriculture. CO_2 emissions cause an important contribution to near-term warming that is not always fully acknowledged in discussions of LLGHGs and SLCFs (Lund et al., 2020).

The global sectoral ranking for near- and long-term global temperature effects is similar to the AR5 assessment despite regional reductions in aerosol precursor emissions between 2008 and 2014. This report has applied updated climate policy metrics for SLCFs and treatment of aerosol-cloud interactions for SO_2, BC and OC (Lund et al., 2020). By far the largest 10-year GSAT effects are from the energy production (fossil fuel mining and distribution), agriculture and waste management (*high confidence*). CH_4 is the dominant contributor in the energy production, agriculture, and waste management sectors. On the 10-year time horizon, other net warming sectors are residential fossil fuel and energy combustion (dominated by CO_2) and aviation and residential biofuel (dominated by SLCFs and cloud) (*medium confidence*). The total residential and commercial sector including biofuel and fossil fuels is the 4th most warming economic sector

ACCEPTED VERSION SUBJECT TO FINAL EDITING

globally on short time horizons of 10-20 years. The energy combustion sector has considerable cooling from high emissions of SO_2 that result in a relatively small net GSAT temperature effect on short time horizons, despite the high CO_2 emissions from this activity. On the 10-year time horizon, global emissions from industry and shipping cause a net cooling effect despite a considerable warming from CO_2 emissions. On the 100-year time horizon, the net effects of agriculture and waste management are small, while energy combustion is the largest individual contributor to warming due to its high CO_2 emissions. The second largest driver of long-term temperature change is industry, demonstrating the importance of non-CO_2 emissions for shaping relative weight over different time frames. Transport contributes a small net warming on the 10-year time horizon that increases by a factor of three on the 100-year time horizon. In contrast, aviation sector contribution to warming shrinks by about a factor of three between the 10- and 100-year time horizons. Results for the 20-year time horizon are provided in the Supplementary Material 6.SM.4. Compared to the 10-year time horizon, there are some changes in ranking, especially of sectors and regions with a strong SO_2 contribution, which decays substantially between 10 and 20 years. Aviation is the sector with most distinct difference between 10 and 20 year time horizons such that the net GSAT effect after 20 years becomes small but negative due to a switch in sign for the NO_x AGTP for this sector and these two time horizons related to the stronger short-lived ozone response than other sectors.

In terms of source regions, the largest contributions to net short-term warming are caused by emissions in Eastern Asia, Latin America and North America, followed by Africa, Eastern Europe and West-Central Asia and South East Asia (*medium confidence*). However, the relative contributions from individual species vary. In East Asia, North America, Europe and South Asia the effect of current emissions of cooling and warming SLCFs approximately balance in the near term and these regions cause comparable net warming effects on 10- and 100-year time horizons (Figure 6.16). In Latin America, Africa and South East Asia and Developing Pacific, CH_4 and BC emissions are currently high while emissions of CO_2 and cooling aerosols are low compared to other regions, resulting in a net warming effect after 10 years that is substantially higher than that of CO_2 alone.

Overall, the global sectors that contribute the largest warming on short time scales are the CH_4-dominated sources, i.e., energy production (fossil fuel mining and distribution), agriculture and waste management (*high confidence*). On short time scales, other net warming sectors are residential fossil fuel and energy combustion (dominated by CO_2) and aviation and residential biofuel (dominated by SLCFs) (*medium confidence*). On short-time scales, global emissions from industry and shipping cause a net cooling effect despite a considerable warming from CO_2 emissions (*high confidence*). On longer time horizons, the sectors that contribute the largest warming are energy combustion and industry due to the large CO_2 emissions (*high confidence*).

6.6.2.3.5 Source attribution of regional air pollution

The attribution of present-day surface $PM_{2.5}$ and O_3 concentrations to sectors and regions (Figure 6.17) is based on 2014 CMIP6 emissions used in the TM5-FASST model (Van Dingenen et al., 2018) that has been widely applied to analyse air quality in regional and global scenarios (Van Dingenen et al., 2009; Rao et al., 2016, 2017; Vandyck et al., 2018; e.g., Harmsen et al., 2020). Regions with largest year 2014 population-weighted annual average surface $PM_{2.5}$ concentrations are South Asia, East Asia, and Middle East. The dominant anthropogenic source of ambient $PM_{2.5}$ in South Asia is residential and commercial sector (biomass and coal fuel-based cooking and heating) with secondary contributions from energy and industry. In East Asia, the main anthropogenic sources of ambient $PM_{2.5}$ are energy, industry and residential sources. Natural sources, predominantly dust, are the most important $PM_{2.5}$ source in the Middle East, Africa and Eurasia, contributing about 40-70% of ambient annual average concentrations (Figure 6.17). Agriculture is an important contributor to ambient $PM_{2.5}$ in Europe and North America, while open biomass burning is a major contributor in South East Asia and Developing Pacific, North America as well as Latin America. These results are consistent with several global and regional studies, where contribution of emission sources to ambient $PM_{2.5}$ or premature mortality was estimated at different scales (Guttikunda et al., 2014; Lelieveld et al., 2015b; e.g., Amann et al., 2017; Qiao et al., 2018; Venkataraman et al., 2018; Wu et al., 2018).

Natural sources contribute more than 50% to surface ozone in all regions except South Asia and South East

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Asia. South Asia, East Asia and the Middle East experience the highest surface ozone levels of all regions. For ozone, the anthropogenic sectoral attribution is more uniform across regions than for $PM_{2.5}$, except for South and Southeast Asia where land transportation plays are larger role and East Asia with most significant contribution from energy and industry. Land transportation and energy are the most important contributors to ozone across many of the regions, with smaller contributions from agriculture, biomass burning, waste management and industry. Open biomass burning is not a major contributor to surface ozone, except for Africa, Latin America and South East Asia where its contribution is estimated at about 5-10% of anthropogenic sources. Relative importance of natural and anthropogenic emission sources on surface ozone have been assessed in several studies (Uherek et al., 2010; Zare et al., 2014; Mertens et al., 2020; Unger et al., 2020) and the results are comparable with the estimates of the TM5-FASST used here.

Residential and commercial cooking and heating is among the most important anthropogenic sources of ambient $PM_{2.5}$, except Middle East and Asia-Pacific Developed (*high confidence*) and agriculture is the dominant source in Europe and North America (*medium confidence*). Energy and industry are important $PM_{2.5}$ contributors in most regions, except Africa (*high confidence*). Energy and land transportation are the major anthropogenic sources of ozone across many world regions (*medium to high confidence*).

[START FIGURE 6.16 HERE]

Figure 6.16: Global-mean surface temperature response 10 and 100 years following one year of present-day (year 2014) emissions. The temperature response is broken down by individual species and shown for total anthropogenic emissions (top), sectoral emissions (left) and regional emissions (right). Sectors and regions are sorted by (high-to-low) net temperature effect on the 10-year time scale. Error bars in the top panel show uncertainty (5-95% interval) in net temperature effect due to uncertainty in radiative forcing only (calculated using a Monte Carlo approach and best estimate uncertainties from the literature - see Lund et al. (Lund et al., 2020) for details). CO2 emissions are excluded from open biomass burning and residential biofuel use due to their unavailability in CEDS and uncertainties around non-sustainable emission fraction. Emissions for 2014 originate from the Community Emissions Data System (CEDS) (Hoesly et al., 2018), except for HFCs which are from Purohit et al. (2020), open biomass burning from van Marle et al. (2017), and aviation H2O which is from Lee et al.(2020b). The split of fossil fuel production and distribution and combustion for energy and residential and commercial fuel use into fossil fuel and biofuel components obtained from the GAINS model (ECLIPSE version 6b dataset). Open biomass burning emissions are not included for the regions. Emission are aggregated into fossil fuel production and distribution (coal mining, oil and gas production, upstream gas flaring, gas distribution networks), agriculture (livestock and crop production), fossil fuel combustion for energy (power plants), industry (combustion and production processes, solvent use loses from production and end use), residential and commercial (fossil fuel use for cooking and heating as well is HFCs leakage from A/C and refrigeration), waste management (solid waste, incl. landfills and open trash burning, residential and industrial waste water), land transportation (road and off-road vehicles, and HFC leakage from A/C and refrigeration equipment), residential and commercial (biofuels use for cooking and heating), open biomass burning (forest, grassland, savannah fires, and agricultural waste burning), shipping (incl. international shipping), and aviation (incl. international aviation). Further details on data sources and processing are available in the chapter data table (Table 6.SM.1).

[END FIGURE 6.16 HERE]

[START FIGURE 6.17 HERE]

Figure 6.17: Emission source-sector attribution of regional population weighted mean concentrations of $PM_{2.5}$ and ozone for present day emissions (year 2014). Regional concentrations and source apportionment calculated with the TM5-FASST model (Van Dingenen et al., 2018) for the 2014 emission data from the Community Emissions Data System (CEDS) (Hoesly et al., 2018) and van Marle et al.(2017) for open biomass burning. $PM_{2.5}$ dust and seasalt are monthly mean climatological average over 2010-2018 from CAMS global reanalysis (EAC4) (Inness et al., 2019), generated using Copernicus Climate Change Service information [January 2020]. Anthropogenic sectors are similar to those in Figures 6.3 and 6.16 except grouping of fossil fuel production, distribution and combustion for energy under “Energy” and

ACCEPTED VERSION SUBJECT TO FINAL EDITING

grouping of use of fossil fuel and biofuel use for cooking and heating under "Residential and Commercial". Further details on data sources and processing are available in the chapter data table (Table 6.SM.1).

[END FIGURE 6.17 HERE]

6.6.3 Past and current SLCF reduction policies and future mitigation opportunities

Several SLCF emission reduction strategies have been explored in the literature or are already pursued as part of the environmental and development policies, including air quality, waste management, energy poverty, and climate change. The effects of various policies and strategies have been addressed in a limited number of modelling studies having different objectives and range from assessment of specific policies and their regional effects (UNEP and WMO, 2011; Shindell et al., 2012a, 2017a, AMAP, 2015a, 2015b; Haines et al., 2017a; UNEP and CCAC, 2018; Harmsen et al., 2019; UNEP, 2019) to large-scale global scenario studies with varying level of SLCF control (Sand et al., 2016; e.g., Rogelj et al., 2018b; Shindell and Smith, 2019). They could be grouped into:

- Projections of future SLCF emissions compatible with the climate mitigation trajectories investigated in the climate model intercomparison projects (respective RCP or SSP scenarios): In such scenarios, when climate change mitigation is considered, it is associated with strong decrease of CO_2 emissions, largely relying on fossil fuel use reduction, the co-emitted SLCFs from combustion and methane from production and distribution of fossil fuels will be reduced proportionally. Depending on carbon price and climate mitigation target, further reduction of methane from waste and agriculture will also be part of such scenarios. Limitations of RCP scenarios, where continuous strengthening of air quality legislation was assumed and therefore lack of futures where global and regional air quality deteriorates, for the analysis of air quality and potential for mitigation of SLCFs have been discussed in literature (e.g., Amann et al., 2013; Von Schneidemesser et al., 2015). SSP scenarios consider various levels of air pollution control, in accordance with their socioeconomic narrative, and thus cover a wider span of SLCF trajectories (Section 6.7). The economical cost of implementation of these scenarios and their co-benefits on air quality and SDGs are assessed in WGIII (Chapter 3) reports.

- Projections of SLCF emissions assuming strong reduction of all air pollutants in the absence of climate mitigation (e.g., the SSP3-LowSLCF scenario); the latter is an idealized simulation of a very ambitious air quality policy where maximum technical potential of existing end-of-pipe technologies is explored in the SSP3-7.0 scenario. Methane reduction can also be part of such sensitivity analysis although methane reductions have not historically been motivated by air pollution concerns.

- Projection of emissions targeting air quality or other development priorities: Anthropogenic emissions source-structure and the level of exposure to pollution and subsequent effects vary significantly from one region to another (section 6.3.2). Therefore, the air quality policy, regional climate impact concerns as well as development priorities, and consequently the level of mitigation of particular SLCF species, will differ regionally and source-wise with respect to the emissions sources, influence of intercontinental transport of pollution, and spatial physical heterogeneities (Lund et al., 2014b; AMAP, 2015a; Sand et al., 2016; Turnock et al., 2016; Sofiev et al., 2018; WMO, 2018). This is also the case at a finer local and regional scale where priorities and scope for SLCF mitigation will differ (e.g., Amann et al., 2017; UNEP, 2019).

- Projections exploring mitigation potential for a particular source or SLCF: These studies focus on the assessment of SLCF reduction potential that can be realised with either existing and proven technologies or extend the scope to include transformational changes needed to achieve further reduction (UNEP and WMO, 2011; Stohl et al., 2015; Velders et al., 2015; Purohit and Höglund-Isaksson, 2017; e.g., Gómez-Sanabria et al., 2018; UNEP, 2019; Höglund-Isaksson et al., 2020; Purohit et al., 2020) – several of these studies are subsequently used for parameterization of the

ACCEPTED VERSION SUBJECT TO FINAL EDITING

models used to develop emission scenarios (e.g., IAM models used in the IPCC process).

In the following subsections, we assess the SLCF mitigation and its effects as identified in regional and global studies evaluating past and current air quality and other SLCF regulations (Sections 6.6.3.1, 6.6.3.2, 6.6.3.3). Development policies, independent from the CMIP6 assessment framework, including peer-reviewed studies and initiatives like UNEP, analysing win-win climate, air quality and SDG motivated strategies are discussed in Section 6.6.3.4. Note that sensitivity studies where impacts of complete removal of particular species are analysed (e.g., Samset et al., 2018) are used sparingly in this assessment. While such analysis can be useful for assessing the effect of a zero-emission commitment (see Chapter 4.7.1.1), they do not correspond to a realistic SLCF mitigation strategy with plausible pace of implementation and removal of co-emitted species (Shindell and Smith, 2019). Discussion of climate and air quality implications of SLCF reductions in SSP scenarios is provided in section 6.7.

6.6.3.1 Climate response to past AQ policies

Air quality policies emerged several decades ago focusing on emission mitigation first driven by local then by regional scale air quality and ecosystem damage concerns, that is, health impacts and acidification and eutrophication. They have made it possible to reduce or limit pollution exposure in many megacities or highly populated regions e.g. in Los Angeles, Mexico City, Houston in North America (Parrish et al., 2011), Santiago in Chile (Gallardo et al., 2018), São Paulo in Brazil (Andrade et al., 2017), Europe (Reis et al., 2012; Crippa et al., 2016; Serrano et al., 2019), and over East Asia during the last decade (Silver et al., 2018; Zheng et al., 2018b). However, very few studies have quantified the impact of these policies on climate. AR5 concluded that air quality control will have consequences on climate including strong regional variability, however, no estimates of impacts of specific air quality policy were available. Since AR5, few studies have provided estimates of climate relevant indicators affected by significant air pollutant burden changes due to air quality policy in selected regions. Turnock et al. (2016) estimated that the strong decrease in NO_x, SO_2 and $PM_{2.5}$ emissions in Europe, induced by air quality policies resulting in implementation of abatement measures since the 1970s, have caused a surface warming of +0.45±0.11°C and increase of precipitation +13±0.8 mm yr^{-1} over Europe, compared to the scenario without such policies. While the temperature increase is likely overestimated since the impact of increase in ammonium nitrate was not considered in this study, the simulated European all-sky TOA radiative effect of the European air pollutant mitigation over the period 1970-2009 is 2.5 times the change in global mean CO_2 radiative forcing over the same period (Myhre et al., 2013b). Other studies found that the recent measures to reduce pollution over China have induced a decrease of aerosols and increase of ozone over east China (Li et al., 2019a, 2020a) resulting in an overall warming effect mainly due to the dominant effect of sulphate reductions in the period 2012-2017 (Dang and Liao, 2019).

6.6.3.2 Recently decided SLCF relevant global legislation

International shipping emissions regulation: from January 2020, a new global standard, proposed by the International Maritime Organisation, limits the sulphur content in marine fuels to 0.5% against previous 3.5% (IMO, 2016). This legislation is considered in the SSP5 and SSP2-4.5 and with a delay of few years in SSP3-LowSLCF, SSP1-1.9, and SSP1-2.6, and in other SSP emission scenarios achieved by mid 21st century. This global measure aims to reduce the formation of sulphate (and consequently $PM_{2.5}$) and largely reduce the health exposure to $PM_{2.5}$ especially over India, East China and coastal areas of Africa and the Middle East (Sofiev et al., 2018). Sofiev et al. (2018) used a high spatial and temporal resolution chemistry-climate model and estimated a net total ERF of +71 mW m^{-2} associated with this measure and due to lower direct aerosol cooling (-3.9 mW m^{-2}) and lower cloud albedo (-67 mW m^{-2}). This value, which correponds to 80% decrease of the cooling effect of shipping induced by about 8 Tg of SO_2 of avoided emissions, is consistent with older estimates which considered similar reduction of emitted sulphur. However, there is considerable uncertainty in the indirect forcing since small changes in aerosols, acting as CCNs in clean environment, can have disproportionally large effects on the radiative balance. Since sulphate is by far the largest component of the radiative forcing (Fuglestvedt et al., 2008) and of surface temperature effect (Figure

ACCEPTED VERSION SUBJECT TO FINAL EDITING

6.16) due to ship emissions over short time scale, limiting the co-emitted SLCFs can not offset the warming by sulphur reductions. The reduction of sulphur emission from shipping is assessed to lead to a slight warming mainly due to aerosol-cloud interactions (*medium evidence, medium agreement*).

Kigali Amendment (UNEP, 2016): With the adoption of the Kigali Amendment to the Montreal Protocol (UN, 1987) in 2016, parties agreed to the phasedown of HFCs, substances that are not ozone depleting but are climate forcing agents (Papanastasiou et al., 2018). Baseline scenarios, in the absence of controls or only pre-Kigali national legislation, projected increased use and emissions of HFCs. All recent baseline projections are significantly higher than those used in the Representative Concentration Pathways (RCP) scenarios ((Meinshausen et al., 2011) and Figure 6.18). There is *low confidence* that the high baseline (assuming absence of controls, lack of technical progress, and high growth) as developed in Velders et al. (2009), resulting in additional warming of about 0.5°C by 2100 (Xu et al., 2013; WMO, 2018), is plausible. Evolution of HFC emissions along the baselines consistent with Velders et al. (2009) and Velders et al (2015) would result in a global average warming, due to HFCs, relative to 2000, of about 0.1-0.12°C by 2050 and 0.35–0.5°C and 0.28–0.44°C by 2100, respectively (Xu et al., 2013). The baseline implementation considered in SSP5-8.5 (see Section 6.7.1.1) is comparable to the lower bound of projections by Velders et al. (2015) (Figure 6.18) and several other studies (Gschrey et al., 2011; Purohit and Höglund-Isaksson, 2017; EPA, 2019; Purohit et al., 2020) and result in additional warming of 0.15-0.3°C by 2100 (Figure 6.22) (*medium confidence*).

Efficient implementation of the Kigali Amendment and national and regional regulations has been projected to reduce global average warming in 2050 by 0.05°–0.07°C (Klimont et al., 2017c; WMO, 2018) and by 0.2–0.4°C in 2100 compared with the baseline (see Figure 2.20 of WMO, 2018). Analysis of SSP scenarios based on an emulator (Section 6.7.3) shows a comparable mitigation potential of about 0.02–0.07°C in 2050 and about 0.1–0.3°C in 2100 (Figure 6.22, SSP5-8.5 versus SSP1-2.6). Furthermore, the energy efficiency improvements of cooling equipment alongside the transition to low global warming potential alternative refrigerants for refrigeration and air-conditioning equipment could potentially increase the climate benefits from the HFC phasedown under the Kigali Amendment (Shah et al., 2015; Höglund-Isaksson et al., 2017; Purohit and Höglund-Isaksson, 2017; WMO, 2018). Purohit et al (2020) estimated that depending on the expected rate of technological development, improving energy efficiency of stationary cooling technologies, and compliance with Kigali Amendment could bring future global electricity-savings of more than 20% of expected world's electricity consumption beyond 2050 or cumulative reduction of about 75-275 Gt CO_2eq over the period 2018-2100 (*medium confidence*). This could potentially double the climate benefits of the HFC phase-down of the Kigali Amendment as well as result in small air quality improvements due to reduced air pollutant emissions from power sector, i.e., 8-16% reduction of $PM_{2.5}$, SO_2, NO_x (Purohit et al., 2020).

6.6.3.3 Assessment of SLCF mitigation strategies and opportunities

There is a consensus in the literature that mitigation of SLCF emissions plays a central role in simultaneous mitigation of climate change, air quality, and other development goals including SDG targets (UNEP and WMO, 2011; Shindell et al., 2012b, 2017a, Rogelj et al., 2014b, 2018b; AMAP, 2015a; Haines et al., 2017a; Klimont et al., 2017c; UNEP and CCAC, 2018; McCollum et al., 2018; Rafaj et al., 2018; UNEP, 2019). There is less agreement in the literature with respect to the actual mitigation potential (or its potential rate of implementation), necessary policies to trigger successful implementation, and resulting climate impacts. Most studies agree that climate policies, especially those aiming to keep warming below 1.5-2°C, trigger large SLCF mitigation co-benefits, (e.g., Rogelj et al., 2014b, 2018b), however, discussion of practical implementation of respective policies and SDGs has only started (Haines et al., 2017a). Note that mitigation scenarios outside of the SSP framework are assessed here while those within the SSPs are assessed in Section 6.7.3.

Focusing on air quality, specifically addressing aerosol SLCFs, by introducing best available technology reducing $PM_{2.5}$, SO_2, NO_x in most Asian countries within the 2030-2050 time frame (a strategy that has indeed shown reduction in $PM_{2.5}$ exposure in China) comes, in many regions, short of national regulatory

ACCEPTED VERSION SUBJECT TO FINAL EDITING

$PM_{2.5}$ concentration standards (often set at 35 μg m^{-3} for annual mean) (UNEP, 2019). Similarly, global studies (Rafaj et al., 2018; Amann et al., 2020) shows that strengthening current air quality policies, addressing primarily aerosols and their precursors, will not allow to achieve WHO air quality guidelines (annual average concentration of $PM_{2.5}$ below 10 μg m^{-3}) in many regions.

A multi-model study (four ESMs and six CTMs) found a consistent response to removal of SO_2 emissions that resulted in a global mean surface temperature increase of 0.69°C (0.4-0.84°C), while mixed results for a global BC-focused deep SLCF reduction, excluding SO_2 and CH_4 mitigation which remain like in the baseline (see ECLIPSE in Figure 6.18), concluding about -0.022°C temperature reduction for the decade 2041-2050; this is derived from their estimate that mitigation of the non-CH_4 species contributed only about 10% of the global temperature reduction for the strategy where also CH_4 mitigation was included (-0.22°C ±0.07°C) (Stohl et al., 2015). These results are consistent with studies analysing similar strategies using emulators (Smith and Mizrahi, 2013; e.g., Rogelj et al., 2014b). Stohl et al. (2015) analysed also the impact of BC-focused mitigation on air quality, estimating large scale regional reduction in $PM_{2.5}$ mean concentration from about 2% in Europe to 20% over India for the decade 2041-2050.

Local response to global reduction can be higher than the global temperature response in particular for regions subjected to rapid changes. Hence, mitigation of rapid warming in the Arctic has been subject to increasing number of studies (Sand et al., 2013a, 2016; Jiao et al., 2014; AMAP, 2015b, 2015a; Mahmood et al., 2016; Christensen et al., 2019). Considering maximum technical mitigation potential for CH_4 globally and an idealized strategy reducing key global anthropogenic sources of BC (about 80% reduction by 2030 and sustained thereafter) and precursors of O_3 was estimated to jointly bring a reduction of Arctic warming, averaged over the 2041-2050 period, between 0.2 and 0.6°C (AMAP, 2015a; Sand et al., 2016). Stohl et al. (2015) have estimated that a global SLCF mitigation strategy (excluding further reduction of SO_2) would lead to about twice as high temperature reduction (-0.44°C (-0.39 to -0.49°C)) in the Arctic than the global response to such mitigation.

While there is robust evidence that air-quality policies, resulting in reduction of aerosols and ozone, can be beneficial for human health but can lead to 'disbenefits' for near-term climate change, such trade-offs in response to climate mitigation policies is less certain (Shindell and Smith, 2019). Recent studies show that very ambitious but plausible gradual phasing out of fossil-fuels in 1.5°C compatible pathways with little or no overshoot, lead to a near-term future warming of less than 0.1°C, when considering associated emission reduction of both warming and cooling species. This suggests that there may not be a strong conflict, at least at the global scale, between climate and air-quality benefits in the case of a worldwide transition to clean energy (Shindell and Smith, 2019; Smith et al., 2019). However, at the regional scale, the changes in spatially variable emission and abundance changes might result in different responses including implications for precipitation, monsoon, etc. (Chapter 8), especially over South Asia (e.g., Wilcox et al., 2020).

Decarbonization of energy supply and end use sectors is among key pillars of any ambitious climate mitigation strategy and it would result in improved air quality owing to associated reduction of co-emitted SLCF emissions (McCollum et al., 2013; Rogelj et al., 2014b; e.g., Braspenning Radu et al., 2016; Rao et al., 2016; Stechow et al., 2016; Lelieveld et al., 2019; Shindell and Smith, 2019). Regional studies (Lee et al., 2016; Shindell et al., 2016; Chen et al., 2018; Li et al., 2018b), where significant CO_2 reductions were assumed for 2030 and 2050, show consistently reduction of $PM_{2.5}$ and ozone concentrations resulting in important health benefits. However, these improvements are not sufficient to bring $PM_{2.5}$ levels in agreement with the WHO air quality guideline in several regions. Amann et al. (2020) and UNEP (2019) highlight that only combination of strong air quality, development, and climate policies, including societal transformations, could pave the way towards achievement of such target at a regional and global level.

At a global level, Rao et al. (2016) showed that climate policies, compatible with Copenhagen pledges and a long-term CO_2 target of 450 ppm, result in important air quality benefits, reducing the share of global population exposed to $PM_{2.5}$ levels above the WHO Tier 1 standard (35 μg m^{-3}) in 2030 from 21% to 5%. The impacts are similar to a strong air quality policy but still leaving large parts of population, especially in Asia and Africa, exposed to levels well above WHO air quality guideline level of 10 μg m^{-3}. The latter can be partly alleviated by combining such climate policy with strong air quality policy. Shindell et al. (2018)

ACCEPTED VERSION SUBJECT TO FINAL EDITING

analysed more ambitious climate mitigation scenarios than Rao et al. (2016) and highlighted the opportunities to improve air quality and avert societal effect associated with warmer climate by accelerated decarbonization strategies. Most climate mitigation strategies compatible with limiting global warming to well below 2°C, rely on future negative CO_2 emissions postponing immediate reduction. Alternatively, a faster decarbonization could allow to achieve a 2°C goal without negative CO_2 emissions and with currently known and effectively applied emission control technologies would have also immediate and significant air quality benefits, reducing premature deaths worldwide (Shindell et al., 2018). For a 2°C compatible pathway, Vandyck et al. (2018) estimated 5% and 15% reduction in premature mortality due to $PM_{2.5}$ in 2030 and 2050, respectively, compared to reference scenarios.

There is robust evidence that reducing atmospheric CH_4 will benefit climate and improve air quality through near-surface O_3 reduction (Fiore et al., 2015; Shindell et al., 2017b) and wide agreement that strategies reducing CH_4 offer larger (and less uncertain) climate benefits than policies addressing BC (Smith and Mizrahi, 2013; Rogelj et al., 2014b, 2018b; Stohl et al., 2015; e.g., Christensen et al., 2019; Shindell and Smith, 2019). SR1.5 (Rogelj et al., 2018b) highlighted the importance of CH_4 mitigation in limiting warming to 1.5 ºC in addition to net zero CO_2 emission by 2050. Implementation of the identified maximum technical mitigation (MTFR) potential for CH_4 globally, estimated at nearly 50% reduction (or 205 Tg CH_4 in 2050) of anthropogenic emissions from the baseline, would lead to a reduction in warming, calculated as the differences between the baseline and MTFR scenario, for the 2036-2050 period of about 0.20±0.02°C globally (AMAP, 2015b). Plausible levels of methane mitigation, achieved with proven technologies, can increase the feasibility of achieving the Paris Agreement goal through slightly slowing down the pace of CO_2 reductions (but not changing the final CO_2 reduction goal) while this benefit is enhanced by the indirect effects of methane mitigation on ozone levels (Collins et al., 2018). Adressing methane mitigation appears even more important in view of recently observed growth in atmospheric concentrations that is linked to increasing anthropogenic emissions (see Section 5.1.1.).

Neither ambitious climate change policy nor air quality abatement policy can automatically yield co-benefits without integrated policies aimed at co-beneficial solutions (Zusman et al., 2013; Schmale et al., 2014b; Melamed et al., 2016), particularly in the energy generation and transport sectors (Rao et al., 2013; Thompson et al., 2016; Shindell et al., 2018; Vandyck et al., 2018). Integrated policies are necessary to yield multiple benefits of mitigating climate change, improving air quality, protecting human health, and achieving several Sustainable Development Goals.

[START BOX 6.2 HERE]

BOX 6.2: SLCF Mitigation and Sustainable Development Goals (SDG) opportunities

Striving to achieve air quality and climate targets will bring significant SLCFs reductions. These reductions contribute first and foremost to attainment of SDGs targeting improved human health and sustainable cities (SDG 3 and 11), specifically related to PM exposure (goals 3.9 and 11.6) (Lelieveld, 2017; Amann et al., 2020) but also access to affordable and clean energy, responsible consumption and production, climate, as well as reducing nutrient losses and consequently protect biodiversity (SDG 7, 12, 13, 14, and 15) (UNEP, 2019; Amann et al., 2020). Furthermore, declining SLCF emissions will result in reduced crop losses (SDG 2; zero hunger) due to decrease of ozone exposure (Feng and Kobayashi, 2009; Ainsworth et al., 2012; Emberson et al., 2018).

However, the design of suitable policies addressing these SDGs can be difficult because of the complexity linking emissions to impacts on human health, ecosystem, equity, infrastructure, and costs. Beyond the fact that several species are co-emitted, interlinkage between species, for example through atmospheric chemistry, can weaken the benefit of emissions reduction efforts. An illustration lies in the recent (2013-2017) reduction of aerosols over China (Silver et al., 2018; Zheng et al., 2018b) resulting from the strategy to improve air quality ("Clean Air Action"), has successfully reduced the level of $PM_{2.5}$ but has led to a concurrent increase in surface ozone, partly due to declining heterogeneous interactions of O_3 precursors with aerosols (Li et al., 2019a; Yu et al., 2019). This side effect on ozone has been addressed since then by

ACCEPTED VERSION SUBJECT TO FINAL EDITING

amending the legislation to target NMVOC sources, especially solvent use. Complex interactions between anthropogenic and biogenic vapours are also at play and reduction of certain SLCFs could possibly promote new particle formation from organic vapours (e.g., Lehtipalo et al., 2018). Finally, a recent example of this complexity is the mixed effects on ozone pollution induced by NO_x decrease during the COVID-19 pandemic (see Cross-Chapter Box 6.1). Thus, the climate and air pollution effects of policies depend strongly on choice of regulated compounds and the degree of reduction. Such policies have to be informed by strong science support, including for example multi-model analyses, e.g., HTAP (UNECE, 2010), AMAP (AMAP, 2015a, 2015b), based on global and regional CCMs, essential to capture the complexity and inform the policy development process.

In addition, pursuing SDG objectives, apparently decoupled from air pollution, such as improved waste management, access to clean energy, or improved agricultural practices, would also stimulate and lead to mitigation of SLCFs (Box 6.2, Figure 1). Amann et al. (2020) shows that a global strategy to achieve the WHO air quality guidelines, cannot only rely on air pollution control but also on a combination of SDG aligned policies. Such actions would include energy efficiency improvements, increased use of renewables, reduction of CH_4 from waste management and agriculture, and CO_2 and CH_4 due to lower fossil fuel consumption, resulting in climate co-benefits. Consideration of SDGs including local air quality co-benefits, creates an opportunity to support and gain acceptance for ambitious climate mitigation (Jakob and Steckel, 2016; Stechow et al., 2016; Vandyck et al., 2018). Such near-term policies targeting SDGs and air quality would enable longer term transformations necessary to achieve climate goals (Chapter 17, WGIII).

[END BOX 6.2 HERE]

In summary, there is *high confidence* that effective decarbonization strategies could lead to air quality improvements but are not sufficient to achieve, in the near term, air quality WHO guideline values set for fine particulate matter), especially in parts of Asia and in some highly polluted regions. Additional policies (e.g., access to clean energy, waste management) envisaged to attain Sustainable Development Goals (SDG) bring complementary SLCF reduction (*high confidence)*. Sustained methane mitigation, wherever it occurs, stands out as an option that combines near and long-term gains on surface temperature (*high confidence)* and leads to air pollution benefit by reducing globally the surface ozone level (*high confidence).*

Cross-Chapter Box 6.1: Implications of COVID-19 restrictions for emissions, air quality and climate

Coordinators:
Astrid Kiendler-Scharr (Germany/Austria), John C. Fyfe (Canada)

Contributors:
Josep G. Canadell (Australia), Sergio Henrique Faria (Spain/Brazil), Piers Forster (UK), Sandro Fuzzi (Italy), Nathan P. Gillett (Canada), Christopher Jones (UK), Zbigniew Klimont (Austria/Poland), Svitlana Krakovska (Ukraine), Prabir Patra (Japan/India), Joeri Rogelj (Austria/Belgium), Bjørn Samset (Norway), Sophie Szopa (France), Izuru Takayabu (Japan), Hua Zhang (China)

In response to the outbreak of COVID-19 (officially the severe acute respiratory syndrome–coronavirus 2 or SARS-CoV-2), which was declared a pandemic on March 11 2020 by the World Health Organization (WHO), regulations were imposed by many countries to contain the spread of COVID-19. Restrictions were implemented on the movement of people, such as closing borders or requiring the majority of population to stay at home, for periods of several months. This Cross Chapter Box assess the influence of the COVID-19 containment on short-lived climate forcers (SLCFs) and long-lived greenhouse gases (LLGHGs) and related implications for the climate. Note that this assessment was developed late in the AR6 WGI process and is based on the available emerging literature.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Emissions

Global fossil CO_2 emissions are estimated to have declined by 7% (*medium confidence*) in 2020 compared to 2019 emissions, with estimates ranging from 5.8% to 13.0% based on various combinations of data on energy production and consumption, economic activity and proxy activity data for emissions and economic activity and proxy activity data for emissions and their drivers (Forster et al., 2020; Friedlingstein et al., 2020; Le Quéré et al., 2020; Liu et al., 2020). However, the concentration of atmospheric CO_2 continued to grow in 2020 compared to previous years (Dlugokencky and Tans, 2021). Given the large natural inter-annual variability of CO_2 (Section 5.2.1), and the small expected impact of emissions in the CO_2 growth rate, there were no observed changes in CO2 concentration that could be attributed to COVID-19 containment (Chevallier et al., 2020; Tohjima et al., 2020).

Global daily CO_2 emissions from fossil fuel sources had a maximum decline of 17% in early April, compared with the mean 2019 levels, and coinciding with the global peak pandemic lockdown (Le Quéré et al., 2020). The reductions in CO_2 emissions in 2020 were dominated by the drop in emissions from surface transport followed, in order of absolute emission reductions, by industry, power, and aviation (Le Quéré et al., 2020; Liu et al., 2020). Residential emissions showed little change (Liu et al., 2020) or rose slightly (Forster et al., 2020; Le Quéré et al., 2020). Aviation had the biggest relative drop in activity accounting. CO_2 emissions due to land-use (based on early and uncertain evidence on deforestation and forest fires) were higher than average in 2020 (Amador-Jiménez et al., 2020).

Using similar methodologies, (Forster et al., 2020) assembled activity data and emissions estimates for other greenhouse gases and aerosols and their precursors. Anthropogenic NO_x emissions, which are largely from the transport sector, are estimated to have decreased by a maximum of 35% in April (*medium confidence*). Species whose emissions are dominated by other sectors, such as CH_4 and NH_3 from agriculture, saw smaller reductions.

Abundances and air quality

Owing to the short atmospheric lifetimes of SLCFs relevant to air quality, changes in their concentrations were detected within few days after lockdowns had been implemented (e.g., Bauwens et al., 2020b; Gkatzelis et al., 2021; Shi et al., 2021; Venter et al., 2020b). The COVID-19 driven economic slowdown has illustrated how complex the relationship is between emissions and air pollutant concentrations due to non-linearity in the atmospheric chemistry leading to secondary compound formation (see also Section 6.1 and Box 6.1) (Kroll et al., 2020).

Several studies have examined the effect of COVID-19 containment on air quality, showing that multi-year datasets with proper statistical/modelling analysis are required to discriminate the effect of meteorology from that of emission reduction (Dhaka et al., 2020; Li et al., 2020b; Wang et al., 2020; Zhao et al., 2020b) . Accounting for meteorological influences and with increasing stringency index, the median observed change in NO_2 decreased from -13% to -48%, and in $PM_{2.5}$ decreased from -10% to -33%, whereas the median change in O_3 increased from 0% to 4% (Gkatzelis et al., 2021). The latter can be explained by the decrease of NO emissions that titrate ozone in specific highly polluted areas, leading to the observed increase in surface O_3 concentration in cities (Huang et al., 2020a; Le et al., 2020; Sicard et al., 2020).

The temporary decrease of $PM_{2.5}$ concentrations should be put in perspective of the sustained reduction (estimated at 30% to 70%), which could be achieved by implementing policies addressing air quality and climate change (see Section 6.6.3). Such sustained reductions can lead to multiple benefits and simultaneously achieve several SDGs (Section 6.6.3). These policies would also result in reduction of ground-level ozone by up to 20% (see Section 6.7.1.3).

Except for ozone, temporary improvement of air quality during lockdown periods was observed in most regions of the world (*high confidence*), resulting from a combination of inter-annual meteorological variability and impact of COVID-19 containment measures (*high confidence*). Estimated air pollution

ACCEPTED VERSION SUBJECT TO FINAL EDITING

reductions associated with lockdown periods are lower than what can be expected from integrated mitigation policy leading to lasting reductions (*medium confidence*).

Radiative forcings

COVID-19 related emission changes primarily exerted effective radiative forcing (ERF) through reduced emission rates of CO_2 and methane, altered abundance of short-lived climate forcers (SLCFs), notably O_3, NO_2 and aerosols, and through other changes in anthropogenic activities, notably a reduction in the formation of aviation-induced cirrus clouds.

Forster et al. (2020) combined the FaIR emulator (see Cross-Chapter Box 7.1) with emission changes for a range of species, relative to a continuation of Nationally Determined Contributions (Rogelj et al., 2017). They found a negative ERF from avoided CO_2 emissions that strengthens through 2020, to -0.01 Wm^{-2}. During the spring lockdown, they found a peak positive ERF of 0.1 Wm^{-2} from loss of aerosol-induced cooling, and a peak negative ERF of -0.04 Wm^{-2} from reductions in tropospheric ozone (from reduced photochemical production via NO_x). Overall, they estimated a net ERF of +0.05 Wm^{-2} for spring 2020, declining to +0.025 Wm^{-2} by the end of the year.

Gettelman et al. (2021) extended Forster et al. (2020) results using two ESMs, and found a spring peak aerosol-induced ERF ranging from 0.12 to 0.3 Wm^{-2}, depending on the aerosol parameterization. They also estimated an ERF of -0.04 Wm^{-2} from loss of contrail warming. Overall, they report a peak ERF of 0.04 to 0.2 Wm^{-2}, and a subsequent decline to around half the peak value.

Two independent ESM studies, Weber et al. (2020) and Yang et al. (2020), found consistent results in time evolution and component contributions, but included fewer forcing components.

The available studies are in broad agreement on the sign and magnitude of contributions to ERF from COVID-19 related emission changes during 2020. The peak global mean ERF, in spring 2020, was [0.025-0.2] Wm^{-2} (*medium confidence*), composed by a positive forcing from aerosol-climate interactions of [0.1-0.3] Wm^{-2}, and negative forcings from CO_2 (-0.01 Wm^{-2}), NO_x (-0.04 Wm^{-2}) and contrail cirrus (-0.04 Wm^{-2}) (*low evidence, medium agreement*). By the end of 2020, the ERF was at half the peak value (*medium confidence*).

Climate responses

Changes in atmospheric composition due to COVID-19 emissions reductions are not thought to have caused a detectable change in global temperature or rainfall in 2020 (*high confidence*). A large ensemble of Earth System Model (ESM) simulations show an ensemble average reduction in Aerosol Optical Depth (AOD) in some regions, notably eastern and southern Asia (Fyfe et al., 2021). This result is supported by observational studies finding decreases in optical depth in 2020 (Gkatzelis et al., 2021; Ming et al., 2021; van Heerwaarden et al., 2021), which may have contributed to observed increases in solar irradiance (van Heerwaarden et al., 2021) or solar clear-sky reflection (Ming et al., 2021).

Model simulations of the response to COVID-19 emissions reductions indicate a small warming of global surface air temperature (GSAT) due to a decrease in sulphate aerosols (Forster et al., 2020; Fyfe et al., 2021), balanced by cooling due to an ozone decrease (Forster et al., 2020; Weber et al., 2020), black carbon decrease (Weber et al., 2020) and CO_2 decrease. It is noted that observational studies report little SO_2 change, at least locally near the surface (Shi et al., 2021) and do not correlate with emission inventory based changes (Gkatzelis et al., 2021). One study suggests a small net warming while another using idealized simulations suggests a small cooling (Weber et al., 2020). Simulated GSAT and rainfall changes are unlikely to be detectable in observations (Samset et al., 2020; Fyfe et al., 2021) (*high confidence*).

Multi-model ESM simulations based on a realistic COVID-19 containment forcing scenario (Forster et al., 2020) indicate a model mean reduction in regional AOD but no discernible response in GSAT (Cross-Chapter Box 6.1 Figure 1).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Scenarios of future emissions following COVID-19 disruption have been examined under a range of hypothetical assumptions (Forster et al., 2020).

[START CROSS-CHAPER BOX 6.1, FIGURE 1 HERE]

Cross-Chapter Box 6.1, Figure 1: **Emission reductions and their effect on aerosols and climate in response to COVID-19.** Estimated reductions in emissions of CO_2, SO_2 and NO_x are shown in panel (a) based on reconstructions using activity data (updated from Forster et al., 2020). Eight Earth System Models (ESMs) performed multiple ensemble simulations of the response to COVID-19 emissions reductions forced with these assumed emission reductions up till August 2020 followed by a constant continuation near the August value to the end of 2020. Emission reductions were applied relative to the SSP2-4.5 scenario. Panel (b) shows ESM simulated AOD at 550nm (only seven models reported this variable). Panel (c) shows ESM simulated GSAT anomalies during 2020; curves denote the ensemble mean result for each model with shading used for ±1 standard deviation for each model. ESM data from these simulations ("ssp245-covid") is archived on the Earth System Grid CMIP6 database. Uncertainty is represented using the simple approach: No overlay indicates regions with high model agreement, where ≥80% of models agree on sign of change; diagonal lines indicate regions with low model agreement, where <80% of models agree on sign of change. For more information on the simple approach, please refer to the Cross-Chapter Box Atlas.1.

[END CROSS-CHAPER BOX 6.1, FIGURE 1 HERE]

[END CROSS-CHAPTER BOX 6.1 HERE]

6.7 Future projections of Atmospheric Composition and Climate response in SSP scenarios

This section assesses the 21st century projections of SLCF emissions, abundances, and responses in terms of climate and air quality following the SSPs (Riahi et al., 2017; Gidden et al., 2019) (also see Chapter 1, Cross-Chapter Box 1.5, and Section 1.6.1.3). The future evolution of atmospheric abundances and the resulting climate and AQ responses is driven mainly by anthropogenic emissions and by natural emissions modulated by chemical, physical and biological processes as discussed in Sections 6.2 and 6.3. Like the RCP scenarios used in AR5, the SSP emission scenarios consider only direct anthropogenic (including biomass burning) emissions and do not project natural emission changes due to climate or land-use changes; ESMs intrinsically consider these biogeochemical feedbacks to varying degrees (Section 6.4.5). We rely on future projections based on CMIP6 ESMs with comprehensive representation of chemistry, aerosol microphysics, and biospheric processes that participated in the ScenarioMIP (O'Neill et al., 2016) and AerChemMIP (Collins et al., 2017). However, due to high computational costs of running coupled ESMs, they cannot be used for quantifying the contributions from individual species, regions and sectors and across the scenarios. Therefore, reduced complexity models (see Box 1.3 and Cross-Chapter Box 7.1), which represent chemistry and complex ESM interactions in parameterized forms updated since the AR5, are also applied here.

6.7.1 Projections of Emissions and Atmospheric Abundances

6.7.1.1 SLCF Emissions and atmospheric abundances

The trajectory of future SLCF emissions is driven by the evolution of socioeconomic drivers described in 1.6.1.1 but dedicated, SSP-specific, air pollution policy storylines can change the regional and global trends (Rao et al., 2017). Additionally, assumptions about urbanization (Jiang and O'Neill, 2017) will affect spatial distribution of emissions and consequently air quality.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Growing urbanization worldwide has strongly modified the spatial distribution and intensity of SLCF emissions. The effect and extent of urbanization on air pollution and other emissions species are captured within Integrated Assessment Models (IAM) at varying levels of complexity. In most cases, models use a combination of proxies and assumptions of end-use efficiency and technological improvement assumptions to estimate emissions species arising from rural-to-urban migration and population growth within cities, utilizing quantifications of urbanization for the SSPs (Jiang and O'Neill, 2017). In addition, spatial patterns of future rural and urban population growth, migration, and decline have been quantified for the SSPs using a gravity model (Jiang and O'Neill, 2017). However, linking these spatial patterns with IAM regional emissions pathways is still an ongoing area of study and has not yet been represented in spatial emissions estimates provided by IAMs (Riahi et al., 2017; Gidden et al., 2019; Feng et al., 2020). As described in Feng et al. (2020), spatial emissions estimates derived for CMIP6 are largely a product of existing spatial patterns of population, but do not vary dynamically in future patterns. To the extend urbanization is accounted for in gridded emissions, IAM native region resolution (varying, for example, from 11 world regions to more than 30, depending on the model) provides urbanization-based dynamics. Despite the interest of studying the effect of well planned, densely populated urban centres, which can help to maximize the benefits of agglomeration, by providing proximity to infrastructure and services, opportunity for energy saving, and provide a frame for air quality control, IAM realizations of SSPs are not sufficient to assess this effect. The opportunities and risks associated with this rapid urbanization for SLCF emissions and air quality are analysed in the Chapter 6 of the WGII report and Chapter 8 of the WGIII report.

All the RCP trajectories started in 2005 relying on the assumption that economic growth will bring rapid strengthening of air pollution legislation effectively reducing emissions of non-methane SLCFs (e.g., Chuwah et al., 2013). While in the long term such trends are expected if more ambitious air pollution control goes on par with the economic growth. The near term developments, however, might be much more diverse across the regions and species as has been observed in the last three decades (Amann et al., 2013; Rafaj et al., 2014; Rafaj and Amann, 2018; Ru et al., 2018), especially in several fast-growing economies, leading to the difference between CMIP6 historical estimates for the post 2000 period (Hoesly et al., 2018) and those used in RCPs (Figure 6.18). Since several SLCFs are also air pollutants, the narrow range of the RCP emissions trajectories in the future allowed for only limited analysis of near-future air quality (Amann et al., 2013; Chuwah et al., 2013; Von Schneidemesser et al., 2015). However, the range of storylines in the SSPs lead to a wider range of assumed pollution control policies in the SSPs (Rao et al., 2017; Riahi et al., 2017). In SSP1 and SSP5, strong air quality policies are assumed to minimize adverse effects of pollution on population and ecosystems. In SSP2, a medium pollution control, with lower than current policy targets, is considered. Only weak, regionally varied, air pollution policies are applied in the SSP3 and SSP4. Additional climate policies introduced to reach defined radiative forcing targets will also affect SLCF emissions. The SSP SLCF emission trajectories (Rao et al., 2017; Gidden et al., 2019) assume a long term coupling of economic growth and specific emission indicators, such as, sectoral emission densities. The pace of change varies across regions and SSPs resulting in a wider range of future air pollutants evolution **(**Figure 6.18**)** reflecting the differences in assumed level of air pollution controls across the regions (Figure 6.19). At the end of the century, the SSP scenarios range is about four times that of RCP for SO_2 and NO_x, two to four times for BC and NMVOC, and up to three times for CO and OC, while indicating slightly smaller range than RCPs for CH_4 (Figure 6.20). The originally developed SSP scenarios (Rao et al., 2017) have been harmonized with the CMIP6 historical emissions (Hoesly et al., 2018) and include updated SO_2 emissions to account for the recent decline in China (Gidden et al., 2019).

All SSP scenarios (Figure 6.18), except SSP3-7.0, project decline in global total emissions for all SLCFs by the end of the 21st century, except for ammonia and for HFCs where Kigali Amendment is not included (see Section 6.6.3.2). Similar to RCPs, ammonia emissions continue to increase in most SSPs, except SSP1 and SSP2, accounting for the expected growth in food demand and a general lack of effective policies targeting agricultural emissions. Additionally, mitigation potential for NH_3 is generally smaller than for other species owing to fugitive and widely distributed sources (Pinder et al., 2006; Klimont and Winiwarter, 2015; Mohankumar Sajeev et al., 2018; Sajeev et al., 2018). Most significant changes of SLCF emissions in the near and long term compared to present day are expected for SO_2 owing to ever more stringent (and enforced) legislation in China's power sector, extended recently to industrial sources (Zheng et al., 2018b; Tong et al., 2020), declining coal use in most SSPs, recently announced stricter emission limits for power

ACCEPTED VERSION SUBJECT TO FINAL EDITING

sector in India, and reduction of sulphur content of oil fuel used in international shipping from 2020 (IMO, 2016). For the lower forcing targets (e.g., SSP1-2.6), the SO_2 trajectories are similar to the RCPs resulting in over 50% to 90% decline by 2050 and 2100, respectively, while for the scenarios with no climate policies, the SSPs show large spread even at the end of the century.

[START FIGURE 6.18 HERE]

Figure 6.18: Global anthropogenic and biomass burning short-lived climate forcer (SLCF) and carbon dioxide (CO_2) emissions from 1850 to 2100 and HFC emissions from 1990 to 2100. Emissions for the Coupled Model Intercomparison Project Phase 6 (CMIP6) for the period 1850-2014 are based on Hoesly et al. (2018) and van Marle et al. (2017), emissions for CMIP5 for the period 1850-2005 are from Lamarque et al. (2010), CO_2 emissions are from EDGAR database (Crippa et al., 2020); CH_4 and HFCs are from (Crippa et al., 2019); and air pollutants are from (EC-JRC / PBL, 2020), Höglund-Isaksson (2012) and Klimont et al. (2017b) for ECLIPSE. Projections originate from the Shared Socio-Economic Pathway (SSP) database (Riahi et al., 2017; Rogelj et al., 2018a; Gidden et al., 2019), Representative Concentration Pathway (RCP) database (van Vuuren et al., 2011), GAINS (CLE – current legislation baseline, KA – Kigali Amendment, MTFR – maximum technical mitigation potential) for HFCs (Purohit et al., 2020), Velders et al. (2015), ECLIPSE (Stohl et al., 2015). Further details on data sources and processing are available in the chapter data table (Table 6.SM.1).

[END FIGURE 6.18 HERE]

[START FIGURE 6.19 HERE]

Figure 6.19: Regional anthropogenic and biomass burning short-lived climate forcer (SLCF) emissions from 1850 to 2100. Emissions for the Coupled Model Intercomparison Project Phase 6 (CMIP6) for the period 1850-2014 are based on Hoesly et al. (2018) and van Marle et al. (2017) and emissions for CMIP5 for the period 1850-2005 are from Lamarque et al. (2010). Projections originate from the Shared Socio-Economic Pathway (SSP) database (Riahi et al., 2017; Rogelj et al., 2018a; Gidden et al., 2019) and Representative Concentration Pathway (RCP) database (van Vuuren et al., 2011). Further details on data sources and processing are available in the chapter data table (Table 6.SM.1).

[END FIGURE 6.19 HERE]

Until mid-century, SSP3-7.0 and SSP5-8.5 scenarios project no reduction in NO_x emissions at the global level with decline in most OECD countries and East Asia, driven by existing legislation in power, industry, and transportation, e.g., Tong et al. (2020), and continued increase in the rest of the world (Figure 6.18 and 6.19). Towards the end of the century, similar trends continue in SSP3-7.0 while emissions in SSP5 decline strongly owing to faster technological progress and stronger air quality action (Rao et al., 2017; Riahi et al., 2017). By 2100, the 'Regional Rivalry' (SSP3) scenario emissions of NO_x (and most other SLCFs, except ammonia) are typically twice as high as next highest SSP projection, both at the global (Figure 6.18) and regional level (Figure 6.19). In emission pathways consistent with Paris Agreement goals, NO_x drops, compared to 2015, by 50% in SSP1-2.6 and by 65% in SSP1-1.9 by 2050, and by 2100 is reduced by about 70%, resulting in global emission levels comparable to 1950s and below the RCP range. Similar reductions are projected in climate mitigation pathways at the regional level, except Africa (less than 50% decline) due to high share of biomass emissions as well as strong growth in population and fossil fuel use. The trends in anthropogenic and biomass burning emissions for other ozone precursors (NMVOC, CO) are similar to that of NO_x.

An additional scenario, based on the SSP3-7.0, has been designed specifically to assess the effect of a strong SLCF emission abatement and is called SSP3-7.0-lowNTCF in the literature (Collins et al., 2017; Gidden et al., 2019). It has been applied in the modelling studies (e.g., AerChemMIP) with or without consideration of additional CH_4 reduction and we refer here to these scenarios, respectively, as SSP3-7.0-lowSLCF-lowCH_4 or SSP3-7.0-lowSLCF-highCH_4. In these scenarios, aerosols, their precursors, and non-methane tropospheric

ACCEPTED VERSION SUBJECT TO FINAL EDITING

ozone precursors are mitigated by applying the same emission factors as in SSP1-1.9.

For global methane emissions, the range is similar for SSPs and RCPs over the entire century (Figure 6.18), with highest projections in SSP3-7.0 (slightly below RCP8.5) estimating doubling of the current emissions and a reduction of about 75% by 2100 in scenarios consistent with 1.5-2°C targets; similar as in RCP2.6. At the regional level, the evolution of CH_4 emissions in climate mitigation scenarios is comparable to RCPs but there are significant differences for some regions with respect to high-emission scenarios. Especially, projection for East Asia differ significantly, the highest SSP3-7.0 is about half of the highest RCP by 2100 (Figure 6.19) which is due to much lower projections of coal use in China driven largely by the last decade efforts to combat poor air quality. At the same time, the SSP scenarios without climate mitigation project faster growth in CH_4 emissions in Africa, Middle East, and Latin America (Figure 6.19) driven by developments in agriculture, oil and gas sectors, and, especially in Africa, waste management. There are significant differences in the assessment and feasibility of rapid CH_4 mitigation. Höglund-Isaksson et al. (2020) review most recent studies and assess feasibility of rapid widespread mitigation, concluding that significant (over 50%) reductions are attainable but feasibility of such reductions could be constrained in the short term due to locked capital. This might have implications for near term evolution assumed in, for example, SSP1-1.9 or SSP3-lowSLCF-lowCH_4, where emissions drop very quickly due to fast decarbonization and reductions in agriculture. Such high reduction potential in agriculture has been also assumed in other studies (Lucas et al., 2007; Harmsen et al., 2019) but is questioned by Höglund-Isaksson et al. (2020) who indicate that widespread implementation (within decades) of policies bringing about institutional and behavioural changes would be important for transition towards very low CH_4 emissions from livestock production.

Global emissions of carbonaceous aerosols are projected to decline in all SSP scenarios (Figure 6.18) except SSP3-7.0. In that scenario, which also has much higher emissions than any of the RCPs, about half of the anthropogenic BC originates from cooking and heating on solid fuels, mostly in Asia and Africa (Figure 6.19), where only limited progress in access to clean energy is achieved. Slow progress in improving waste management, high coal use in energy and industry, and no further progress in controlling diesel engines in Asia, Africa, and Latin America contributes most of the remaining emissions resulting in about 90% of anthropogenic BC emitted in non-OECD world by 2100 in SSP3-7.0. Similar picture emerges for OC but with larger importance of waste management sector and biomass burning and lower impact of transportation and industry developments. Since scenarios compliant with Paris Agreement goals (SSP1-1.9 or SSP1-2.6; see Section 1.6.1) include a widespread access to clean energy already by 2050, the global and regional emissions of BC decline by 70-75% by 2050 and 80% by 2100. The decline in residential sector (about 90% by 2050 and over 95% by 2100) is accompanied by a strong reduction in transport (over 98%) and decarbonization of industry and energy sector. About 50% of remaining BC emissions in SSP1-1.9 or SSP1-2.6 is projected to originate from waste and open biomass burning of which open burning of residues represent a significant part. Some studies suggest this might be pessimistic as, for example, efficient waste management (consistent with SDG goals) could potentially eliminate open burning of solid waste (Gómez-Sanabria et al., 2018), which accounts for over 30% of BC emissions in SSP1-1.9 in 2050 or 2100.

The SSP scenarios draw on the HFCs projections developed by Velders et al. (2015) considering, in climate mitigation scenarios, the provisions of the Kigali Amendment (2016) to the Montreal Protocol leading to phasedown of HFCs (Papanastasiou et al., 2018) (see Section 6.6.3.2). The SSP scenarios without climate mitigation (e.g, SSP3-7.0, SSP5-8.5) show a range of 3.2-5.3 Gt CO_2-eq yr^{-1} in 2050 and about 4-7.2 Gt CO_2-eq yr^{-1} by 2100 while in deep climate mitigation scenarios (e.g., SSP1-1.9), consistent with the 1.5-2°C targets, they are expected to drop to 0.1-0.3 and 0.1-0.35 GtCO_2-eq yr^{-1}, respectively (Figure 6.19). In SSP1-1.9, the extent of reduction and its pace is more ambitious than current estimates of the effect of fully implemented and enforced Kigali Amendment (Figure 6.19) (Höglund-Isaksson et al., 2017; Purohit and Höglund-Isaksson, 2017). The best representation of the HFC emission trajectories in the SSP framework compliant with the Kigali Amendment is the SSP1-2.6 and the baseline (including only pre-Kigali national legislation; 6.6.3) is best represented by SSP5-8.5 (see Figure 6.19). However, since HFC emissions in SSPs were developed shortly after the Kigali Amendment had been agreed, none of these projections represents accurately the HFC emission trajectory corresponding to the phase-out emission levels agreed to in the Kigali Amendment (Meinshausen et al., 2020), leading to *medium confidence* in the assessment of the

ACCEPTED VERSION SUBJECT TO FINAL EDITING

benefits of the Kigali Amendment when using SSP projections for HFCs.

The SSP SLCF trajectories reflect the effect of recent legislation and assumed evolution thereof in the longer term, however, they do not necessarily reflect the full mitigation potential for several SLCFs, within particular SSPs (Figure 6.18), that could be achieved with air quality or SDG targeted policies (Amann et al., 2013; Rogelj et al., 2014a; Haines et al., 2017b; Klimont et al., 2017c; Rafaj and Amann, 2018; Shindell et al., 2018; Tong et al., 2020). Such policies could bring more rapid mitigation of SLCFs, independent of the climate strategy (also see Section 6.6.3).

The projections of future SLCF abundances typically follow their emissions trajectories except for SLCFs that are formed from precursor reactions (e.g., tropospheric ozone) or are influenced by biogeochemical feedbacks (See 6.2.2 and 6.4.5). According to multi-model CMIP6 simulations, total column ozone (reflecting mostly stratospheric ozone) is projected to return to 1960s values by the middle of the 21st century under the SSP2-4.5, SSP3-7.0, SSP4-3.4, SSP4-6.0 and SSP5-8.5 scenarios (Keeble et al., 2021). ESMs project increasing tropospheric ozone burden over the 2015-2100 period for the SSP3-7.0 scenario (Figure 6.4) (Griffiths et al., 2020), there is, however, a large spread in the magnitude of this increase reflecting structural uncertainties associated with the model representation of processes that influence tropospheric ozone. Sources of uncertainties in SLCF abundance projections include scenario uncertainties, or parametric and structural uncertainties in the model representation of the processes affecting simulated abundances with implications for radiative forcing and air quality. The evolution of methane abundances in SSP scenarios, for example, is derived from integrated assessment models (IAMs) which do not include the effects from biogeochemical feedbacks (e.g., climate-driven changes in wetland emissions) (Meinshausen et al., 2020) introducing uncertainty.

In summary, in SSPs, in addition to the socio-economic development and climate mitigation policies shaping the GHG emission trajectories, the SLCF emission trajectories are also steered by varying levels of air pollution control originating from SSP narratives and independent from climate mitigation. Consequently, SSPs span a wider range of SLCF emissions than considered in the RCPs, better covering the diversity of future options in air pollution management and SLCF-induced climate effects (*high confidence*). In addition to SSP-driven emissions, the future evolution of SLCFs abundance is also sensitive to chemical and biogeochemical feedbacks involving SLCFs, particularly natural emissions, whose magnitude and sign are poorly constrained.

6.7.1.2 Future evolution of surface ozone and PM concentrations

The projection of air quality relevant abundances (surface ozone and $PM_{2.5}$) under the SSP scenarios are assessed here. Future changes in global and regional annual mean surface ozone and $PM_{2.5}$ driven by the evolution of emissions as well as climate change have been quantified by CMIP6 models analysed in AerChemMIP (Allen et al., 2020; Turnock et al., 2020; Allen et al., 2021).

[START FIGURE 6.20 HERE]

Figure 6.20: Projected changes in regional annual mean surface ozone (O_3) (ppb) from 2015 to 2100 in different shared socio-economic pathways (SSPs). Each panel represents values averaged over the corresponding land area (except for Global) shown on the map in Figure 6.7. Solid colored lines and shading indicate the multi-model mean and ±1 σ across the available CMIP6 models (Turnock et al., 2020; Allen et al., 2021) for each scenario. Changes are relative to annual mean values calculated over the period 2005-2014 from the historical experiment as indicated in the top left of each regional panel along with ±1 σ. For each model all available ensemble members are averaged before being used to calculate the multi-model mean. Ozone changes are also displayed in the Interactive Atlas. Further details on data sources and processing are available in the chapter data table (Table 6.SM.1).

[END FIGURE 6.20 HERE]

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Surface ozone increases continuously until 2050 across most regions in SSP3-7.0 and SSP5-8.5, (Turnock et al., 2020), particularly over Eastern Asia, Southern Asia, Middle East, Africa and South East Asia and developping Pacific where this increase can reach and even exceed 5ppb for annual mean averaged over land areas (Figure 6.20). After 2050, surface ozone concentrations decrease in SSP5-8.5, reaching levels below there 2005-2014 levels in most regions but and level off or continue to increase under SSP3-7.0.This increase in surface ozone in the SSP5-8.5 scenario occurs despite emissions decrease of several ozone precursors because of is due to CH_4 emissions increase until about 2080 in the absence of climate mitigation. Ozone decreases over all regions in response to strong emissions mitigation in SSP1-1.9 and SSP1-2.6 (Turnock et al., 2020), with decreases of 5 to10 ppb as soon as 2030 in North America, Europe, Eurasia, Eastern Asia, Middle East and Southern Asia in their annual means over land areas . In most regions surface ozone is reduced slightly or remains near present day values in the middle of the road scenario, SSP2-4.5. In 2100, the largest differences in surface ozone changes across the scenarios occur for the Middle East, Southern Asia and Eastern Asia with differences ranging up to 40 ppb between SSP3-7.0 and SSP1-1.9 at the end of the century. Despite discrepancies in the magnitude of changes, especially over North America, Europe, Eurasia, Eastern Asia and Southern Asia, the models are in high agreement regarding the signs of the changes with are thus assessed as of *high confidence*.

The strong abatement of ozone precursor emissions (except those of CH_4) (SSP3-7.0-lowSLCF-highCH_4) lead to a decrease of global average surface ozone by 15% (6 ppb) between 2015 and 2055 (Allen et al., 2020) and ozone decreases in all regions except Southern Asia. However, this decrease is two times larger when CH_4 emissions are abated simultaneously (SSP3-7.0-lowSLCF-lowCH_4), underlying the importance of methane emission reduction as an important lever to reduce ozone pollution (*high confidence*) (see also 6.6.4).

[START FIGURE 6.21 HERE]

Figure 6.21: Future changes in regional 5-year mean surface $PM_{2.5}$ from 2015 to 2100 in different shared socio-economic pathways (SSPs). $PM_{2.5}$ stands for micrograms per cubic meter of aerosols with diameter less than 2.5 μm and is calculated by summing up individual aerosol mass components from each model as: black carbon + particulate organic matter + sulphate + 0.25 * sea salt + 0.1 * dust. Since not all CMIP6 models reported nitrate aerosol, it is not included here. See Figure 6.20 for further details. $PM_{2.5}$ changes are also displayed in the Interactive Atlas. Further details on data sources and processing are available in the chapter data table (Table 6.SM.1).

[END FIGURE 6.21 HERE]

A decrease in surface $PM_{2.5}$ concentrations is estimated for SSP1-1.9, SSP1-2.6 and SSP2-4.5 (Turnock et al., 2020) (Figure 6.21). A decrease in $PM_{2.5}$, is also projected in SSP5-8.5 which does not consider any climate mitigation but has a strong air pollution control. The decrease is largest in the regions with the highest 2005-2014 mean concentrations (Middle East, South Asia and East Asia). Under the SSP3-7.0 scenario, $PM_{2.5}$ is predicted to increase or remain at near present-day values across Asia; regions where present-day concentrations are currently the highest. There is large model spread over regions with large natural aerosol sources, for example, in North Africa, where dust sources are important. The mitigation of non-methane SLCFs in the SSP3-7.0-lowSLCF-highCH_4 scenario is predicted to reduce $PM_{2.5}$ by 25% (in 2055, relative to the SSP3-7.0 scenario) over global land surface areas (Allen et al., 2020).

The magnitude of the annual mean change in surface ozone and $PM_{2.5}$ for all the SSPs (accounting for both emission and climate change) is greater than that expected from climate change in isolation (Turnock et al., 2020). The uncertainty in the projections comes from how natural emissions will respond to climate change. However, multiple lines of evidence (along with those from Sections 6.2.2, 6.5, and 6.7.1) provide *high confidence* (compared to *medium* in AR5) that changes in emissions, and in particular human-induced emissions, will drive future air pollution levels rather than physical climate change.

In summary, future air pollution levels are strongly driven by precursor emission trajectories in the SSPs

ACCEPTED VERSION SUBJECT TO FINAL EDITING

with substantial reductions in global surface ozone and PM (when air pollution and climate change are both strongly mitigated, e.g., SSP1-2.6) to no improvement and even degradation (when no climate change mitigation and only weak air pollution control are considered, SSP3-7.0) (*high confidence*). In the latter case, PM levels are estimated to increase until 2050 over large parts of Asia and surface ozone pollution worsens over all continental areas throughout the whole century (*high confidence*). In scenarios without climate change mitigation but with strong air pollution control (SSP5-8.5), high methane levels hamper the decline in global surface ozone in the near term and only PM levels decrease (*high confidence*).

6.7.2 Evolution of future climate in response to SLCF emissions

6.7.2.1 Effects of SLCFs on ERF and climate response

This section assesses how the different spatial and temporal evolution of SLCF emissions in the SSPs affects the future global and regional ERFs, and GSAT and precipitation responses. In CMIP6, only a very limited set of simulations (all based on the SSP3-7.0 scenario) have been carried out with coupled ESMs to specifically address the future role of SLCFs (Collins et al., 2017), see also Sections 4.3 and 4.4. Note that the ScenarioMIP simulations (Section 4.3) include the SLCF emissions (as shown in Figures 6.18 and 6.19), however they cannot be used to quantify the effect of individual forcers. Coupled ESMs can in principle be used for this through a series of sensitivity simulations (e.g. Allen et al., 2020, 2021), but the amount of computer time required has made this approach prohibitive across the full SSP range. Therefore, to quantify the contribution from emissions of individual forcers spanning the range of the SSP scenarios to GSAT response, the analysis is mainly based on estimates using a two-layer emulator configuration derived from the medians of MAGICC7 and FaIRv1.6.2 (see Section 1.5.3.4, Cross Chapter Box 7.1, and Supplementary Material 7.SM5.2). The contribution from SLCFs to changes in GSAT have been calculated based on the global mean ERF for the various components as assessed in section 7.3.5, using the two-layer emulator for the climate response (Cross Chapter Box 7.1 and Supplementary Material 7.SM5.2).

The projections of GSAT for a broad group of forcing agents (aerosols, methane, tropospheric ozone, and HFCs with lifetimes lower than 50 years) for the SSP scenarios shows how much of the future warming or cooling (relative to 2019) can be attributed to the SLCFs (Figure 6.22). Note that during the first two decades, some of these changes in GSAT are due to emissions before 2019, in particular for the longer lived SLCFs such as methane and HFCs (see also Figure 6.15). The scenarios SSP3-7.0-lowSLCF-highCH_4 and SSP3-7.0-lowSLCF-lowCH_4 are special cases of the SSP3-7.0 scenario with strong, but realistic, reductions in non-methane SLCFs and all SLCFs respectively (Gidden et al., 2019).

As discussed in sections 6.2, 6.3 and 6.4, there are uncertainties relating emissions of SLCFs to changes in abundance (see Box 6.2) and further to ERF, in particular for aerosols and tropospheric ozone. Furthermore there are uncertainties related to the climate sensitivity, i.e., the relation between ERF and change in GSAT. Uncertainties in the ERF are assessed in Chapter 7 and calibrated impulse response function includes also the assessed range (see Box 7.1). There are also uncertainties related to the efficacies of the different SLCFs and time scales for the response, in particular for regional emissions (Schwarber et al., 2019; Yang et al., 2019b) that cannot be accounted for with the simple models used here.

[START FIGURE 6.22 HERE]

Figure 6.22: Time evolution of the effects of short-lived climate forcers (SLCFs) and hydrofluorocarbons (HFCs) on global surface air temperature (GSAT) across the WGI core set of Shared Socio-Economic Pathways (SSPs). Effects of net aerosols, methane, tropospheric ozone and HFCs (with lifetimes <50years), relative to year 2019 and to year 1750. The GSAT changes are based on the assessed historic and future evolution of Effective Radiative Forcing (Section 7.3.5). The temperature responses to the ERFs are calculated with an impulse response function with an equilibrium climate sensitivity of 3.0°C for a doubling of atmospheric CO2 (feedback parameter of -1.31 W m-2 °C-1, see CC-Box 7.1). Uncertainties are 5-95% ranges. The vertical bars to the right in each panel show the uncertainties for the GSAT change between 2019 and 2100. Further details on data sources and processing are available in the

ACCEPTED VERSION SUBJECT TO FINAL EDITING

chapter data table (Table 6.SM.1).

[END FIGURE 6.22 HERE]

Historical emissions have been updated until 2019 (see Supplementary Material of Chapter 7, 7.SM.1.3.1) and used for ERF for calculating GSAT in Figure 6.22. Year 2019 has been chosen as the base year to be consistent with the attributed temperature changes since 1750 (Figure 7.8). The warming attributed to SLCFs (methane, ozone and aerosols) over the last decade (Figure 7.8) constitutes about 30% of the peak SLCF driven warming in the most stringent scenarios (SSP1), in good agreement with Shindell and Smith (2019), and supported by the recent observed decline in AOD (Section 2.2.6).

From 2019 and until about 2040, SLCFs and HFCs will contribute to increase GSAT in the WG1 core set of SSP scenarios, with a *very likely* range of 0.04-0.41°C relative to 2019. The warming is most pronounced in the strong mitigation scenarios (i.e., SSP1-1.9 and SSP1-2.6) due to rapid cuts in aerosols. In the scenario SSP3-7.0, there is no reduction of aerosols until mid-century and it is the increases in methane and ozone that give a net warming in 2040. The warming is similar in magnitude to the SSP1-scenarios, in which the reduction in aerosols is the main driver. Contributions to warming from methane, ozone, aerosols and HFCs make SSP5-8.5 the scenario with the highest warming in 2040 and throughout the century.

After about 2040, it is *likely* that across the scenarios the net effect of the removal of aerosols is a further increase in GSAT. However, their contribution to the rate of change decreases towards the end of the century (from up to 0.2°C per decade before 2040 to about 0.03 °C per decade). After 2040, the changes in methane, HFCs and tropospheric ozone become equally important as the changes in the aerosols for the GSAT trends. In the low emission scenarios (SSP1-1.9 and SSP1-2.6), the contribution to warming from the SLCFs peaks around 2040 with a *very likely* range of 0.04°C-0.34°C. After the peak, the reduced warming from reductions in methane and ozone dominates, giving a best total estimate warming induced by SLCF and HFC changes of 0.12°C and 0.14°C respectively, in 2100, with a *very likely* range of -0.07°C to + 0.45°C (Figure 6.22). However, in the longer term towards the end of the century there are very significant differences between the scenarios. In SSP3-7.0 there is a near linear warming due to SLCFs of 0.08°C per decade, while for SSP5-8.5 there is a more rapid early warming. In SSP3-7.0, the limited reductions in aerosols, but a steady increase in methane, HFCs and ozone lead to a nearly linear contribution to GSAT reaching a best estimate of 0.5°C in 2100. Contributions from methane and ozone decrease towards 2100 in SSP5-8.5, however the warming from HFCs still increase and the SSP5-8.5 has the largest SLCF and HFC warming in 2100 with a best estimate of of 0.6°C. In the SSP2-4.5 scenario, a reduction in aerosols contributes to about 0.3°C warming in 2100, while contributions from ozone and methane in this scenario are small.

The simplified approach used to estimate the contributions to GSAT in Figure 6.22 have been supplemented with ESM simulations driven by the two versions of the SSP3-7.0-lowSLCF scenario (Section 6.7.1.1). Results from five CMIP6 ESMs with fully interactive atmospheric chemistry and aerosols for the high-methane scenario show (Allen et al., 2020, 2021) that these reductions in emissions of air pollutants would lead to additional increase in GSAT by 2055 relative to 2015 compared to the standard SSP3-7.0 scenario, with a best estimate of 0.23 ± 0.05°C, and a corresponding increase in global mean precipitation of 1.3 ± 0.17% (note that uncertainties from the work of Allen et al here and elsewhere are reported as twice standard deviation). Including methane mitigation (SSP3-7.0-lowSLCF-lowCH_4) would lead to a small increase in global precipitation (0.7 ± 0.1 %) by mid-century despite a decrease in GSAT (see 6.7.3), which is related to the higher sensitivity of precipitation to sulphate aerosols than greenhouse gases (Allen et al., 2021) (also see Section 8.2.1).

Regionally inhomogeneous ERFs can lead to regionally dependent responses (see section 6.4.3). Mitigation of non-methane SLCFs over the period 2015 to 2055 (SSP3-7.0-lowSLCF-highCH_4 versus SSP3-7.0) will lead to positive ERF over land regions (Allen et al., 2020). There are large regional differences in the ERF from no significant trend over Northern Africa to about 0.5 W m^{-2} $decade^{-1}$ for South Asia. The differences are mainly driven by differences in the reductions of sulphate aerosols. There is not a strong correspondence between regional warming and the ERF trends. As expected, the sensitivity (temperature change per unit

ACCEPTED VERSION SUBJECT TO FINAL EDITING

ERF) increases towards higher latitudes due to climate feedbacks and teleconnections. Regionally, the warming rates are higher over continental regions, with highest increase in temperatures for Central and Northern Asia and the Arctic in 2055 relative to 2015. The models agree on increasing global mean trend in precipitation due to SLCFs, however precipitation trends over land are more uncertain (Allen et al., 2020), in agreement with the relationship between aerosol and precipitation trends assessed in Chapter 8.

ESM estimates of future concentrations of various SLCFs vary considerably even when using the same future emission scenarios which is related to sources of model structural uncertainty in the several physical, chemical and natural emission model parameterisations. The general uncertainties in understanding and representing chemical and physical processes governing the life cycle of SLCFs (see Box 6.1) necessarily also applies to simulations of future concentrations and ERF. In addition, how the models are able to simulate climate changes (i.e., circulation and precipitation) that affects the dispersion and removal of SLCFs constitute a structural uncertainty in the models. Also SLCF related climate feedbacks (e.g., NO_x from lightning or BVOCs from vegetation) (Section 6.4.5) add to the uncertainty.

In the near term (2035-2040), it is *unlikely* that differences in the socio-economic developments (as embedded in the SSPs) can lead to a discernible difference in the net effect of changes of SLCFs on GSAT. This is because the intermodel spread in the estimated net effect of SLCFs on GSAT is as large as difference between the scenarios due to compensating effects of change in emissions leading to cooling and warming. However, in the longer term there is *high confidence* that the net warming of the SLCFs will be lower in the mitigation scenarios (SSP1-1.9 and SSP1-2.6 that include reductions in methane emissions) than in the high-emission scenarios (SSP3-7.0 and SSP5-8.5).

6.7.2.2 Effect of regional emissions of SLCFs on GSAT

For SLCFs with lifetimes shorter than typical mixing times in the atmosphere (days to weeks), the effects on secondary forcing agents (e.g. tropospheric ozone, sulphate and nitrate aerosols) depend on where and when the emissions occur due to non-linear chemical and physical processes. Also, the effective radiative forcing following a change in concentrations depends on the local conditions (see Sections 6.2, 6.3 and 6.4). While the emulators used for GSAT projections shown in figure 6.22 do not take the regional perspective into account, the set of simulations performed within the Hemispheric Transport of Air Pollutants phase two (HTAP2) project (Galmarini et al., 2017) allows for this perspective. The results from the chemistry-transport model OsloCTM3 taking part in in HTAP-2 have been used by Lund et al. (2020) to derive regional specific absolute global warming potentials (AGTPs, cf. (Aamaas et al., 2016)) for each emitted SLCF and each HTAP-2 region. With this set of AGTPs Lund et al. (2020) estimate the transient response in GSAT to the regional anthropogenic emissions. There are important differences in the contributions to GSAT in 2040 and 2100 (relative to 2020) between the regions and scenarios mainly due to the differences in mixture of emitted SLCFs (Figure 6.23). There is overall good agreement between the total net contribution from all regions to GSAT and the estimate based on global ERF and the two-layer emulator (Figure 6.22).

In the low and medium emission scenarios (SSP1-2.6 and SSP2-4.5), the warming effects of the SLCFs on GSAT are dominated by emissions in North America, Europe, and East Asia (Figure 6.23). In SSP1-2.6 the emissions of all SLCFs in all regions decrease and the net effect of the changes in SLCFs from all of these three regions is an increase in GSAT of about 0.02°C (per region) in 2040 and about 0.04°C in 2100. For SSP2-4.5 emissions of most SLCFs continue to increase in South Asia (see Figure 6.19), leading to a net cooling in the near term (-0.03°C in 2040), while in 2100, North America, Europe, East and South Asia all contribute to a warming, most pronounced from East Asia (0.05°C). In the SSP3-7.0 scenario the net effect of SLCFs in all regions is an enhanced warming towards the end of the century. Methane then becomes the dominant SLCF, and Africa is the region contributing the most to predicted global warming in 2100 (0.24°C). In SSP5-8.5, methane emissions increase in North America, Europe and Africa, while there is a decrease in the Asian regions. For North America and Europe, the methane increase combined with a reduction in aerosol leads to highest net contribution to GSAT in this scenario (0.06 and 0.04°C in 2100, respectively). The high growth in methane makes Africa the region with the largest contribution to future

ACCEPTED VERSION SUBJECT TO FINAL EDITING

warming by SLCFs (0.18°C in 2100 versus 2020) in this scenario.

[START FIGURE 6.23 HERE]

Figure 6.23: Contribution from regional emissions of short-lived climate forcers (SLCFs) to changes in global surface air temperature (GSAT) in 2040 (upper row) and 2100 (lower row), relative to 2020 for four Shared Socio-economic Pathways (SSP). Adapted from (Lund et al., 2020). NOx, CO, and VOC account for the impact through changes in ozone and methane, NOx additionally includes the impact through formation of nitrate aerosols. BC, SO_2 and OC accounts for the direct aerosol effect (aerosol-radiation interactions), as well as an estimate of the semi-direct effect for BC due to rapid adjustments and indirect effect (aerosol-cloud interactions) of sulfate aerosols. Regions are the same as shown in the map in Figure 6.7. Further details on data sources and processing are available in the chapter data table (Table 6.SM.1).

[END FIGURE 6.23 HERE]

6.7.3 Effect of SLCFs mitigation in SSP scenarios

Air quality policies lead to a decrease in emissions of both warming and cooling SLCFs. Here we assess the contribution of SLCFs to the total warming (including also the long-lived climate forcers) in the case of stringent SLCF mitigation to improve air quality in scenarios with continued high use of fossil fuels (e.g., SSP3-7.0-lowSLCF and SSP5-8.5). Conversely, we also assess the effect on air quality of strategies aiming to mitigate air pollution or climate change under the SSP3-7.0 framework (using the SSP3-7.0-lowSLCF-lowCH_4, SSP3-7.0-lowSLCF-highCH_4 and SSP3-3.4 scenarios).

As illustrated in Figure 6.24 (Section 6.7.2.2) and in Figure 2.2 of SR1.5 (Rogelj et al., 2018a), the total aerosol ERF change in stringent mitigation pathways is expected to be dominated by the effects from the phase-out of SO_2 contributing to a warming. Recent emission inventories and observations of trends in AOD (see Section 2.2.6 and 6.2.1) show that it is *very likely* that there have been reductions in global SO_2 emissions and in aerosol burdens over the last decade. Here, we use 2019 as the reference year rather than the 'Recent Past' defined as the average over 1995–2014 (Section 4.1) in order to exclude the recent emission reductions when discussing the different possible futures.

The role of the different SLCFs, and also the net of all the SLCFs relative to the total warming in the scenarios, is quite different across the SSP scenarios varying with the summed levels of climate change mitigation and air pollution control (Figure 6.24). In the scenario without climate change mitigation but with strong air pollution control (SSP5-8.5) all the SLCFs (CH_4, aerosols, tropospheric O_3) and the HFCs (with lifetimes less than 50 years) add to the warming, while in the strong climate change and air pollution mitigation scenarios (SSP1-1.9 and SSP1-2.6), the emission controls act to reduce methane, ozone and BC, and these reductions thus contribute to cooling. In all scenarios, except SSP3-7.0, emission controls lead to a reduction of the aerosols relative to 2019, causing a warming. However, the warming from aerosol reductions is stronger in the SSP1 scenarios (with best estimates of 0.21°C in 2040 and 0.4°C in 2100 in SSP1-2.6) because of higher emission reductions from stronger decrease of fossil-fuel use in these scenario than in SSP5-8.5 (0.13°C in 2040 and 0.22°C in 2100). The changes in methane abundance contribute a warming of 0.14°C in SSP5-8.5, but a cooling of 0.14°C in SSP1-2.6 by the end of the 21st century relative to 2019. Furthermore, under SSP5-8.5, HFCs induce a warming of 0.06°C with a *very likely* range of [0.04 to 0.08°C] in 2050 and 0.2 [0.1 to 0.3]°C by the end of the 21st century, relative to 2019, while under SSP1-2.6, warming due to HFCs is negligible (below 0.02°C) (*high confidence*). This assessment relies on these estimates, which are based on updated ERFs and HFC lifetimes. It is in accordance with previous estimates (Section 6.6.3.2) of the efficiency of implementation of the Kigali Amendment and national regulations. It is *very likely* that under a stringent climate and air pollution mitigation scenario (SSP1-2.6), the warming induced by changes in methane, ozone, aerosols, and HFCs towards the end of 21st century, will be very low compared with the warming they would cause under SSP5-8.5 scenario (0.14 °C in SSP1-2.6 versus 0.62 °C in SSP5-8.5).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

For the SSP3-7.0-lowSLCF-highCH_4 and SSP3-7.0-lowSLCF-lowCH_4 scenarios, a five ESM ensemble has been analyzed relative to the standard SSP3-7.0 scenario (Allen et al., 2020, 2021). For SSP3-7.0-lowSLCF-highCH_4, in which the methane emissions are as in the standard SSP3-7.0 scenario, (Allen et al., 2021) found an enhanced global mean surface warming of 0.23±0.05 °C by mid-century and 0.21±0.03 °C by 2100 relative to the warming in the standard SSP3-7.0 scenario. Including also strong mitigation of methane emissions, the same models (Allen et al., 2021) find that the warming is off-set resulting in a net cooling of 0.15±0.05 °C at mid-century (2050-2059) and 0.50±0.02 °C at the end of the century (2090-2099) relative to SSP3-7.0.

There is *robust evidence* and *high agreement* that non-methane SLCFs mitigation measures, through reductions in aerosols and non-methane ozone precursors to improve air quality (SSP3-7.0-lowSLCF-highCH_4 versus SSP3-7.0), would lead to additional near-term warming with a range of 0.1°C -0.3°C. Methane mitigation which also reduces tropospheric ozone, stands out as an option that combines near and long term gains on surface temperature (*high confidence)*. With stringent but realistic methane mitigation (SSP3-7.0-lowSLCF-lowCH_4), it is *very likely* that warming (relative to SSP3-7.0) from non-methane SLCFs can be off-set (Figure 6.24 and Allen et al., 2021). Due to the slower response to the methane mitigation, this offset becomes more robust over time and it is *very likely* to be an offset after 2050. However, when comparing to present day, it is *unlikely* that that methane mitigation can fully cancel out the warming over the 21st century from reduction of non-methane cooling SLCFs.

The SSP3 storyline assumes 'regional rivalry' (see 1.6.1.1) with weak air pollution legislation and no climate mitigation and is compared here against SSP3-7.0-lowSLCF-lowCH_4 (strong air pollution control) and SSP3-3.4 (the most ambitious climate policy feasible under SSP3 narrative). In the SSP3-3.4 scenario, all emissions follow the SSP3-7.0 scenario until about 2030 and then deep and rapid cuts in fossil fuel use are imposed (Fujimori et al., 2017). In the case of climate mitigation, such as in the SSP3-3.4 scenario, the decrease of SLCFs emissions is a co-benefit from the targeted decrease of CO_2 (when SLCFs are co-emitted), but also directly targeted as in the case of methane. For SLCFs, this means that emissions of aerosols and methane increase until 2030 and are reduced fast thereafter (Fujimori et al., 2017). The effect on GSAT (relative to 2019) is shown in Figure 6.22 and 6.24. The net GSAT response to the SLCFs is dominated by the aerosols, with an initial cooling until 2030, then a fast rebound for 15 years followed by a very moderate warming reaching 0.21°C in 2100. The ozone change causes a slight cooling (up to 0.06°C), in contrast to the warming in the SSP3-7.0-lowSLCF-highCH_4 scenario in which the methane emissions increase until 2100.

[START FIGURE 6.24 HERE]

Figure 6.24: Effects of short-lived climate forcers (SLCFs) and hydrofluorocarbons (HFCs) on global surface air temperature (GSAT) across the WGI core set of Shared Socio-Economic Pathways (SSPs). Effects of net aerosols, methane, tropospheric ozone, and hydrofluorocarbons (HFCs; with lifetimes < 50 years), are compared with those of total anthropogenic forcing for 2040 and 2100 relative to year 2019. The GSAT changes are based on the assessed historic and future evolution of Effective Radiative Forcing (Section 7.3.5). The temperature responses to the ERFs are calculated with an impulse response function with an equilibrium climate sensitivity of 3.0°C for a doubling of atmospheric CO_2 (feedback parameter of -1.31 W m^{-2} °C^{-1}, see Cross-Chapter Box 7.1). Uncertainties are 5-95% ranges. The scenario total (grey bar) includes all anthropogenic forcings (long- and short-lived climate forcers, and land use changes) whereas the white points and bars show the net effects of SLCFs and HFCs and their uncertainties. Further details on data sources and processing are available in the chapter data table (Table 6.SM.1).

[END FIGURE 6.24 HERE]

To assess the effect of dedicated air quality versus climate policy on air quality, $PM_{2.5}$ and ozone indicators were estimated for three SSP3 scenarios by applying a widely used approach for the analysis of air quality implications for given emission scenarios (Rao et al., 2017; Van Dingenen et al., 2018; Vandyck et al., 2018)

ACCEPTED VERSION SUBJECT TO FINAL EDITING

and whose sensitivity of surface concentrations to emission changes is comparable to ESMs ensemble (see Supplementary Material 6.SM.5). The assessment shows that both strong air pollution control and strong climate mitigation, implemented independently, lead to large reduction of exposure to $PM_{2.5}$ and ozone by the end of the century (Figures 6.25, 6.26) (*high confidence*). However, implementation of air pollution control, relying on the deployment of existing technologies, leads to benefits more rapidly than climate mitigation (*high confidence*), which requires systemic changes and is thus implemented later in this scenario. Notably, under the underlying SSP3 context, significant parts of the population remain exposed to air quality exceeding the WHO guidelines for $PM_{2.5}$ over the whole century (*high confidence*), in particular in Africa, Eastern and Southern Asia, Middle East and for ozone only small improvement in population exposure is expected in Africa and Asia. Confidence levels here result from expert judgement on the whole chain of evidence.

[START FIGURE 6.25 HERE]

Figure 6.25: Effect of dedicated air pollution or climate policy on population-weighted $PM_{2.5}$ concentrations (µg m^{-3}) and share of population (%) exposed to different $PM_{2.5}$ levels across selected world regions. Thresholds of 10 µg m^{-3} and 35 µg m^{-3} represent the WHO air quality guideline and the WHO interim target 1, respectively; WHO (2017). Results are compared for SSP3-7.0 (no major improvement of current legislation is assumed), SSP3-LowSLCF (strong air pollution controls are assumed), and a climate mitigation scenario SSP3-3.4; details of scenario assumptions are discussed in Riahi et al. (2017) and Rao et al. (2017). Analysis performed with the TM5-FASST model (Van Dingenen et al., 2018) using emission projections from the Shared Socio-Economic Pathway (SSP) database (Riahi et al., 2017; Rogelj et al., 2018a; Gidden et al., 2019). Further details on data sources and processing are available in the chapter data table (Table 6.SM.1).

[END FIGURE 6.25 HERE]

[START FIGURE 6.26 HERE]

Figure 6.26: Effect of dedicated air pollution or climate policy on population-weighted ozone concentrations (SOMO0; ppb) and share of population (%) exposed to chosen ozone levels across ten world regions. Results are compared for SSP3-7.0 (no major improvement of current legislation is assumed), SSP3-Low NTCF (strong air pollution controls are assumed), and a climate mitigation scenario (SSP3-3.4); details of scenario assumptions are discussed in Riahi et al. (2017) and Rao et al. (2017). Analysis performed with the TM5-FASST model (Van Dingenen et al., 2018) using emission projections from the Shared Socio-Economic Pathway (SSP) database (Riahi et al., 2017; Rogelj et al., 2018a; Gidden et al., 2019). Further details on data sources and processing are available in the chapter data table (Table 6.SM.1).

[END FIGURE 6.26 HERE]

In summary, the warming induced by SLCF changes is stable after 2040 in the WG1 core set of SSP scenarios associated with lower global air pollution as long as methane emissions are also mitigated, but the overall warming induced by SLCF changes is higher in scenarios in which air quality continues to deteriorate (caused by growing fossil fuel use and limited air pollution control) (*high confidence*). In the SSP3-7.0 context, applying an additional strong air pollution control resulting in reductions in anthropogenic aerosols and non-methane ozone precursors would lead to an additional near-term global warming of 0.1°C with a *very likely* range of [-0.05 to 0.25]°C (compared with SSP3-7.0 for the same period). A simultaneous methane mitigation consistent with SSP1's stringent climate mitigation policy implemented in the SSP3 world, could entirely alleviate this warming and even lead to a cooling of 0.1°C with a *very likely* range of [-0.1 to 0.20]°C (compared with SSP3-7.0 for the same period). Across the SSPs, the reduction of CH_4, ozone precursors and HFCs can make a 0.2°C [0.1–0.4]°C difference on GSAT in 2040 and a 0.8°C [0.5–1.3]°C difference at the end of the 21st century (Figure 6.24), which is substantial in the context of the 2015 Paris

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Agreement. Sustained methane mitigation, wherever it occurs, stands out as an option that combines near and long term gains on surface temperature (*high confidence)* and leads to air pollution benefit by reducing globally the surface ozone level (*high confidence)*.

Strong air pollution control as well as strong climate change mitigation, implemented independently, lead to large reduction of the exposure to air pollution by the end of the century (*high confidence*). Implementation of air pollution control, relying on the deployment of existing technologies, leads more rapidly to air quality benefits than climate change mitigation which requires systemic changes but, in both cases, significant parts of the population remain exposed to air pollution exceeding the WHO guidelines.

6.8 Perspectives

Ice-core analyses can now inform trends for more SLCFs over the last millennium (such as light NMVOCs or CO) and more proxies are available to inform about past emissions. However, preindustrial levels of SLCFs are still relatively poorly constrained. In addition, recent trends in abundances of the various types of aerosols and of NMVOCs suffer from the scarcity of observation networks in various parts of the world, in particular in the Southern Hemisphere. Such network development is necessary to record and understand the evolution of atmospheric composition.

Assessment of the future air pollution changes at the urban level require the use of high resolution model to properly account for non-linearities in chemistry, specific urban structures, local meteorology as well as temporal and spatial variations in emissions and population exposure. To assess the relevance of air pollution reduction policies, regional air quality models are necessary and are still not implemented in many developing countries. To properly apply such models, the quality of spatialized emission inventories is essential, but the production of accurate emission inventories remain a challenge for lots of rapidly growing urban areas. The emission reporting now planned in the official mandate of the Task Force on National Greenhouse Gas Inventories (TFI) can be a step in this direction if accompanied by efforts on emission spatial distribution. An integrated modelling framework associating global and high-resolution chemistry-transport models with shared protocols is missing to allow a systematic assessment of future changes on air quality at this scale.

In parallel, opportunities of progress may emerge from big data acquisition. Big data and their mining can inform practices related to emissions or can document pollution levels if associated with massive deployment of low cost sensors through citizen science. New generation satellite data will as well give access to sub-km scale air pollution observations.

A systematic emission modeling framework is needed to assess the LLGHG emission changes associated with SLCFs reductions induced by air pollution control in the SSP framework. The SLCF mediated effects of large-scale technology deployment to allow climate mitigation, such as hydrogen energy production, carbon capture and storage though amine filters or changes in agricultural practices to limit GHG emissions and/or produce bioenergy are also not considered in the emission scenarios.

Since AR5, the complexity of ESMs has increased to include many chemical and biogeochemical processes. These lasts are necessary to quantify non-CO_2 biogeochemical feedbacks on the Earth System resulting from climate driven changes in atmospheric chemistry and SLCF emissions from natural systems and, in turn, impacts of SLCFs on biogeochemical cycles. Enhanced understanding of the biological, chemical and physical processes based on experimental and observational work has facilitated advances in the ESMs. However, assessment of non-CO_2 biogeochemical feedbacks and SLCF effects on land and aquatic ecosystem productivity still remains challenging due to the multiple complex processes involved and limitations in observational constraints to evaluate the skill of ESMs in realistically simulating the processes. Advances will come from better understanding of the processes and mechanisms, in particular at the component interfaces. The development of high resolution ESMs will facilitate their evaluation against high resolution observations.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Frequently Asked Questions

FAQ 6.1: What are short-lived climate forcers and how do they affect the climate?

Short-lived climate forcers (SLCFs) are compounds such as methane and sulphate aerosols that warm or cool the Earth's climate over shorter time scales – from days to years – than greenhouse gases like carbon dioxide, whose climatic effect lasts for decades, centuries or more. Because SLCFs do not remain in the atmosphere for very long, their effects on the climate are different from one region to another and can change rapidly in response to changes in SLCF emissions. As some SLCFs also negatively affect air quality, measures to improve air quality have resulted in sharp reductions in emissions and concentrations of those SLCFs in many regions over the few last decades.

The SLCFs include gases as well as tiny particles called *aerosols*, and they can have a warming or cooling effect on the climate (FAQ 6.1, Figure 1). Warming SLCFs are either greenhouse gases (e.g., ozone or methane) or particles like black carbon (also known as soot), which warm the climate by absorbing energy and are sometimes referred to as *short-lived climate pollutants.* Cooling SLCFs, on the other hand, are mostly made of aerosol particles (e.g., sulphates, nitrates and organic aerosols) that cool down the climate by reflecting away more incoming sunlight.

Some SLCFs do not directly affect the climate but produce climate-active compounds and are referred to as precursors. SLCFs are emitted both naturally and as a result of human activities, such as agriculture or extraction of fossil fuels. Many of the human sources, particularly those based on combustion, produce SLCFs at the same time as carbon dioxide and other long-lived greenhouse gases. Emissions have increased since the start of industrialization, and humans are now the dominant source for several SLCFs and SLCF precursors, such as sulphur dioxide (which produces sulphates) and nitrogen oxides (which produce nitrates and ozone), despite strong reductions over the last few decades in some regions from efforts to improve air quality.

The climatic effect of a chemical compound in the atmosphere depends on two things: (1) how effective it is at cooling or warming the climate (its *radiative efficiency*) and (2) how long it remains in the atmosphere (its *lifetime*). Because they have high radiative efficiencies, SLCFs can have a strong effect on the climate even though they have relatively short lifetimes of up to about two decades after emission. Today, there is a balance between warming and cooling from SLCFs, but this can change in the future.

The short lifetime of SLCFs constrains their effects in both space and time. First, of all the SLCFs, methane and the short-lived halocarbons persist the longest in the atmosphere: up to two decades (FAQ 6.1, Figure 1). This is long enough to mix in the atmosphere and to spread globally. Most other SLCFs only remain in the atmosphere for a few days to weeks, which is generally too short for mixing in the atmosphere, sometimes even regionally. As a result, the SLCFs are unevenly distributed and their effects on the climate are more regional than those of longer-lived gases. Second, rapid (but sustained) changes in emissions of SLCFs can result in rapid climatic effects.

In addition to the direct warming and cooling effects, SLCFs have many other consequences for the climate system and for air quality (see FAQ 6.2). For instance, deposition of black carbon on snow darkens its surface, which subsequently absorbs more solar energy, leading to more melting and more warming. Aerosols also modify the properties of clouds, which has indirect cooling effects on the climate and causes changes in local rainfall (see FAQ 7.2). Climate models indicate that SLCFs have altered atmospheric circulation on local and even hemispheric scales (e.g., monsoons) as well as regional precipitation. For instance, recent observations show that regional weather is influenced by strong regional contrasts in the evolution of aerosol concentrations, particularly over South and East Asia.

Although policies to limit climate change and discussions of the so-called *remaining carbon budgets* primarily focus on carbon dioxide (see FAQ 5.4), SLCFs can significantly affect temperature changes. It is therefore important to understand how SLCFs work and to quantify their effects. Because reducing some of

ACCEPTED VERSION SUBJECT TO FINAL EDITING

the SLCF emissions, such as methane, can simultaneously reduce warming effects and adverse effects on air quality as well as help attaining Sustainable Development Goals, mitigation of SLCFs is often viewed as a favourable 'win-win' policy option.

[START FAQ 6.1, FIGURE 1 HERE]

FAQ 6.1, Figure 1: Main short-lived climate forcers, their sources, how long they exist in the atmosphere, and their relative contribution to global surface temperature changes between 1750 and 2019 (area of the globe). By definition, this contribution depends on the lifetime, the warming/cooling potential (radiative efficiency), and the emissions of each compound in the atmosphere. Blue indicates cooling and orange warming. Note that, between 1750 and 2019, the cooling contribution from aerosols (blue diamonds and globe) was approximately half the warming contribution from carbon dioxide.

[END FAQ 6.1, FIGURE 1 HERE]

FAQ 6.2: What are the links between limiting climate change and improving air quality?

Climate change and air quality are intimately linked. Many of the human activities that produce long-lived greenhouse gases also emit air pollutants, and many of these air pollutants are also 'short-lived climate forcers' that affect the climate. Therefore, many options for improving air quality may also serve to limit climate change and vice versa. However, some options for improving air quality cause additional climate warming, and some actions that address climate change can worsen air quality.

Climate change and air pollution are both critical environmental issues that are already affecting humanity. In 2016, the World Health Organization attributed 4.2 million deaths worldwide every year to ambient (outdoor) air pollution. Meanwhile, climate change impacts water resources, food production, human health, extreme events, coastal erosion, wildfires, and many other phenomena.

Most human activities, including energy production, agriculture, transportation, industrial processes, waste management and residential heating and cooling, result in emissions of gaseous and particulate pollutants that modify the composition of the atmosphere, leading to degradation of air quality as well as to climate change. These air pollutants are also *short-lived climate forcers* – substances that affect the climate but remain in the atmosphere for shorter periods (days to decades) than long-lived greenhouse gases like carbon dioxide (see FAQ 6.1). While this means that the issues of air pollution and climate change are intimately connected, air pollutants and greenhouse gases are often defined, investigated and regulated independently of one another in both the scientific and policy arenas.

Many sources simultaneously emit carbon dioxide and air pollutants. When we drive our fossil fuel vehicles or light a fire in the fireplace, it is not just carbon dioxide or air pollutants that are emitted, but always both. It is therefore not possible to separate emissions into two clearly distinct groups. As a result, policies aiming at addressing climate change may have benefits or side-effects for air quality, and vice versa.

For example, some short-term 'win-win' policies that simultaneously improve air quality and limit climate change include the implementation of energy efficiency measures, methane capture and recovery from solid waste management and oil and gas industry, zero-emission vehicles, efficient and clean stoves for heating and cooking, filtering of soot (particulate matter) for diesel vehicles, cleaner brick kiln technology, practices that reduce burning of agricultural waste, and the eradication of burning of kerosene for lighting.

There are, however, also 'win-lose' actions. For example, wood burning is defined as carbon neutral because a tree accumulates the same amount of carbon dioxide throughout its lifetime as is released when wood from that tree is burned. However, burning wood can also result in significant emissions of air pollutants, including carbon monoxide, nitrogen oxides, volatile organic compounds, and particulate matter, that locally

or regionally affect the climate, human health and ecosystems (FAQ 6.2, Figure 1). Alternatively, decreasing the amount of sulphate aerosols produced by power and industrial plants and from maritime transport improves air quality but results in a warming influence on the climate, because those sulphate aerosols contribute to cooling the atmosphere by blocking incoming sunlight.

Air quality and climate change represent two sides of the same coin, and addressing both issues together could lead to significant synergies and economic benefits while avoiding policy actions that mitigate one of the two issues but worsen the other.

[START FAQ 6.2, FIGURE 1 HERE]

FAQ 6.2, Figure 1: Links between actions aiming to limit climate change and actions to improve air quality. Greenhouse gases and aerosols (orange and blue) can affect directly climate. Air pollutants (bottom) can affect the human health, ecosystems and climate. All these compounds have common sources and sometimes interact with each other in the atmosphere which makes impossible to consider them separately (dotted grey arrows).

Figures

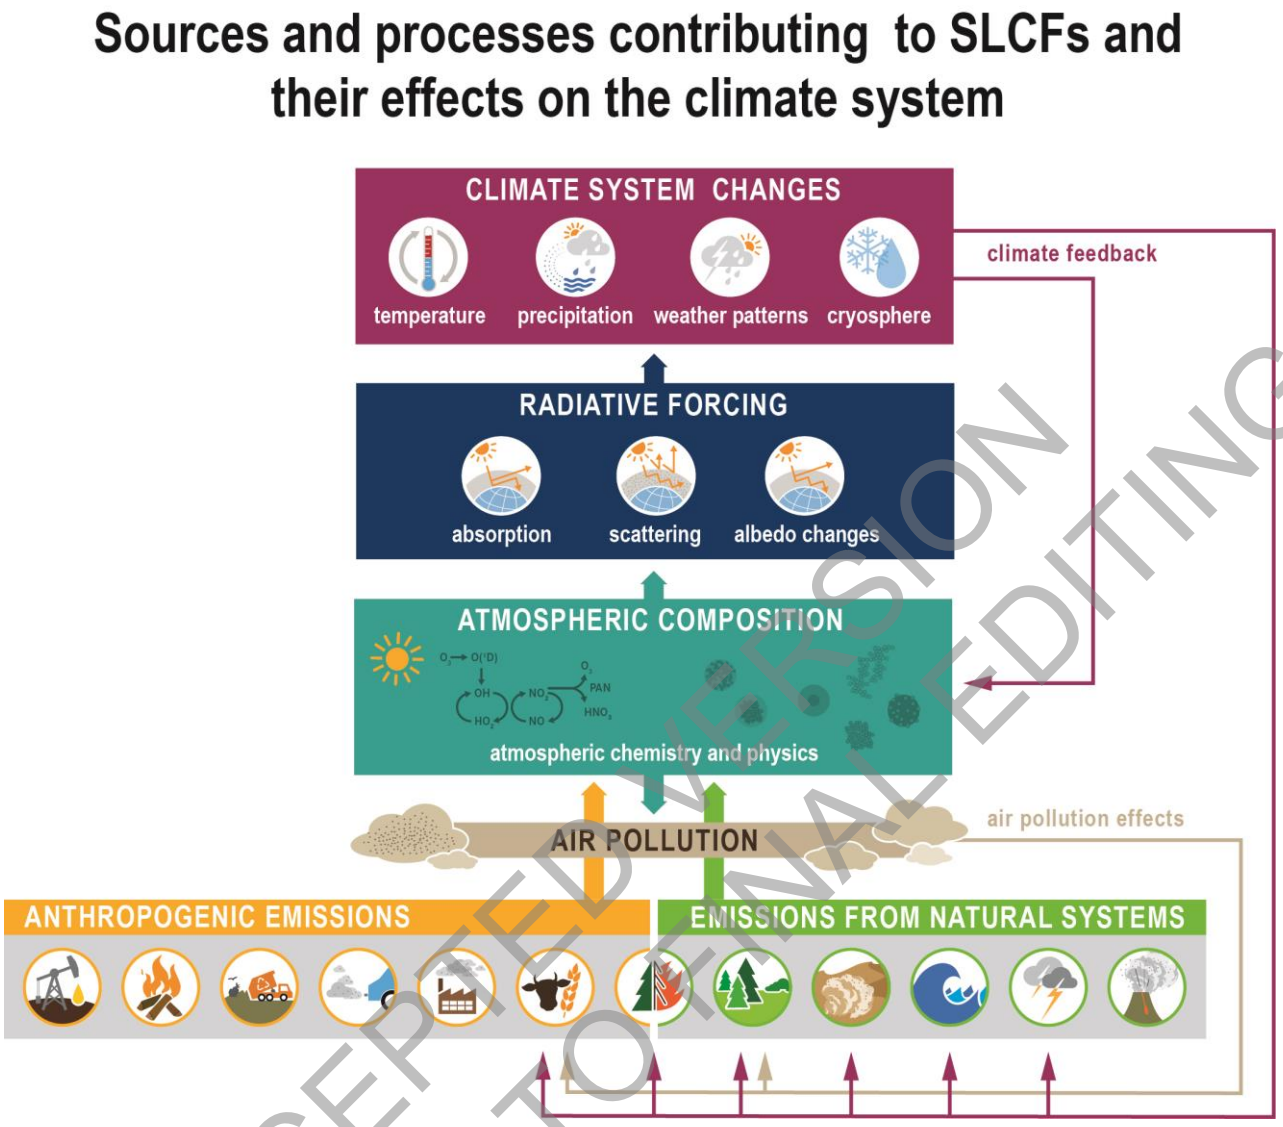

Figure 6.1: **Sources and processes leading to atmospheric short-lived climate forcer (SLCF) burden and their interactions with the climate system**. Both direct and indirect SLCFs and the role of atmospheric processes for the lifetime of SLCFs are depicted. Anthropogenic emission sectors illustrated are fossil fuel exploration, distribution and use, biofuel production and use, waste, transport, industry, agricultural sources, and open biomass burning. Emissions from natural systems include those from open biomass burning, vegetation, soil, oceans, lightning, and volcanoes. SLCFs interact with solar or terrestrial radiation, surface albedo, and cloud or precipitation system. The radiative forcing due to individual SLCF can be either positive or negative. Climate change induces changes in emissions from most natural systems as well as from some anthropogenic emission sectors (e.g. agriculture) leading to a climate feedback (purple arrows). Climate change also influences atmospheric chemistry processes, such as chemical reaction rates or via circulation changes, thus affecting atmospheric composition leading to a climate feedback. Air pollutants influence emissions from terrestrial vegetation, including agriculture (the grey arrow).

Figure 6.3: Relative regional and sectoral contributions to the present day (year 2014) anthropogenic emissions of Short Lived Climate Forcers (SLCFs). Emission data are from the Community Emissions Data System (CEDS) (Hoesly et al., 2018). Emissions are aggregated into the following sectors: fossil fuel production and distribution (coal mining, oil and gas production, upstream gas flaring, gas distribution networks), fossil fuel combustion for energy (power plants), residential and commercial (fossil and biofuel use for cooking and heating), industry (combustion and production processes, solvent use losses from production and end use), transport (road and off-road vehicles), shipping (including international shipping), aviation (including international aviation), agriculture (livestock and crop production), waste management (solid waste, including landfills and open trash burning, residential and industrial waste water), and other. Further details on data sources and processing are available in the chapter data table (Table 6.SM.1).

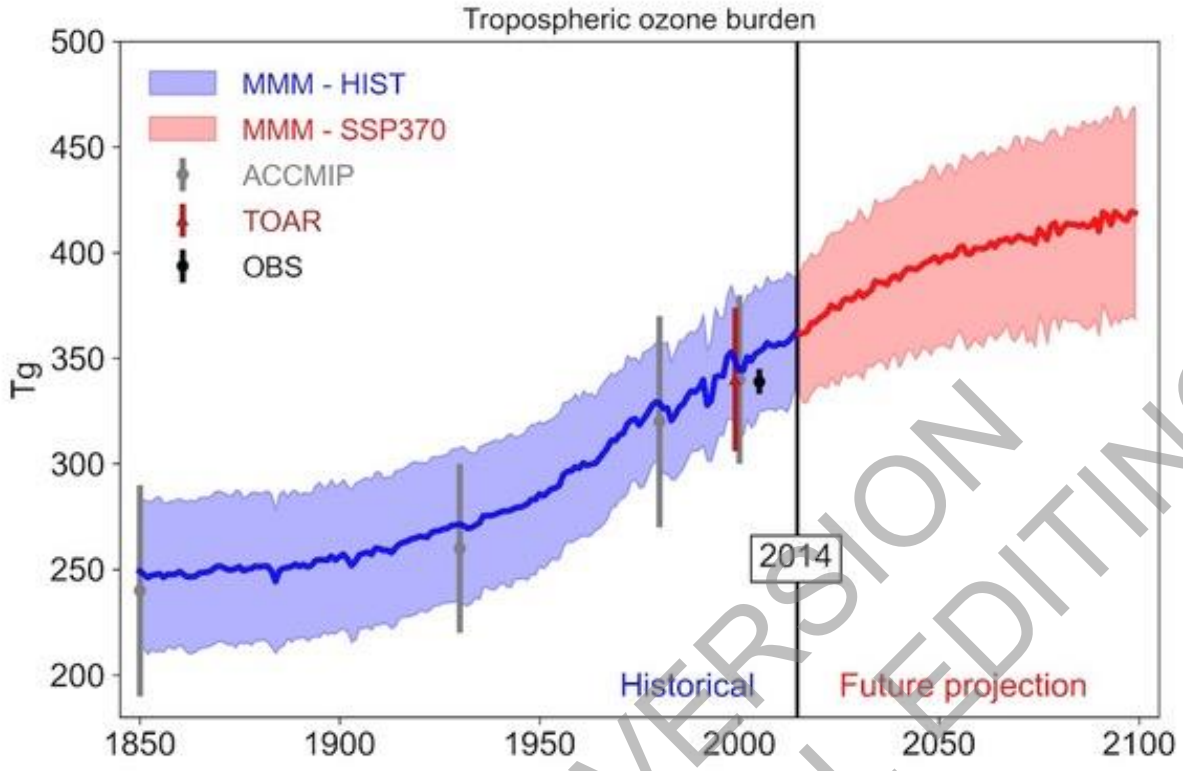

Figure 6.4: **Time evolution of global annual mean tropospheric ozone burden (in Tg) from 1850 to 2100**. Multi-model means for CMIP6 historical experiment (1850-2014) from UKESM1-LL-0, CESM2-WACCM, MRI-ESM2-0, GISS-E2.1-G and GFDL-ESM4 and for ScenarioMIP SSP3-7.0 experiment (2015-2100) are represented with their intermodel standard deviation (±1 σ , shaded areas). Observation based global tropospheric ozone burden estimate (from Table 6.3) is for 2010-2014. Tropospheric Ozone Assessment Report (TOAR) multi-model mean value (from Table 6.3) is for 2000 with a ±1 σ error-bar. Atmospheric Chemistry and Climate Model Intercomparison Project (ACCMIP) multi-model means are for 1850, 1930, 1980 and 2000 time-slices with ±1 σ error-bars. The troposphere is masked by the tropopause pressure calculated in each model using the WMO thermal tropopause definition. Further details on data sources and processing are available in the chapter data table (Table 6.SM.1).

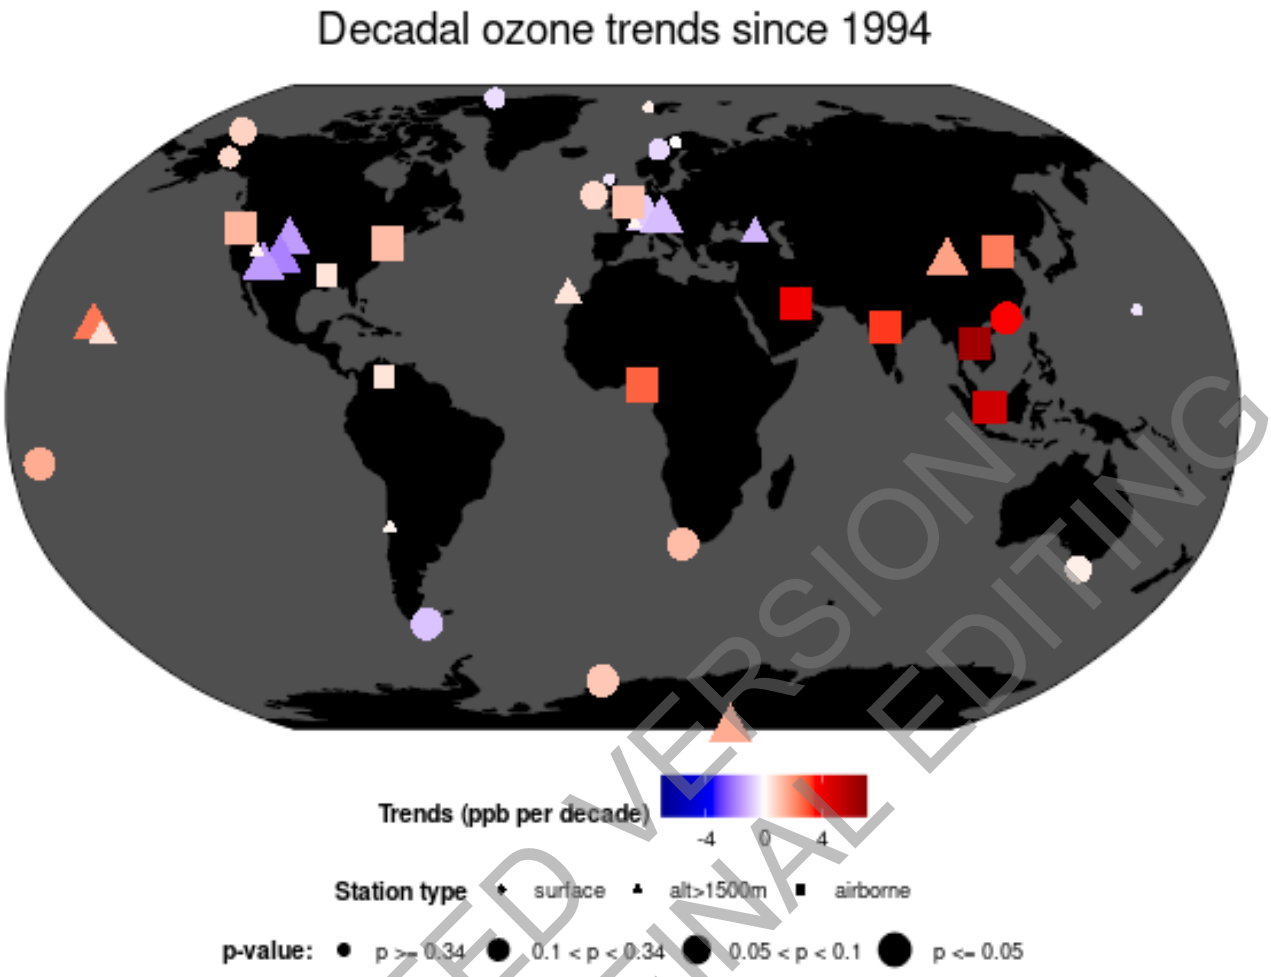
ACCEPTED VERSION SUBJECT TO FINAL EDITING



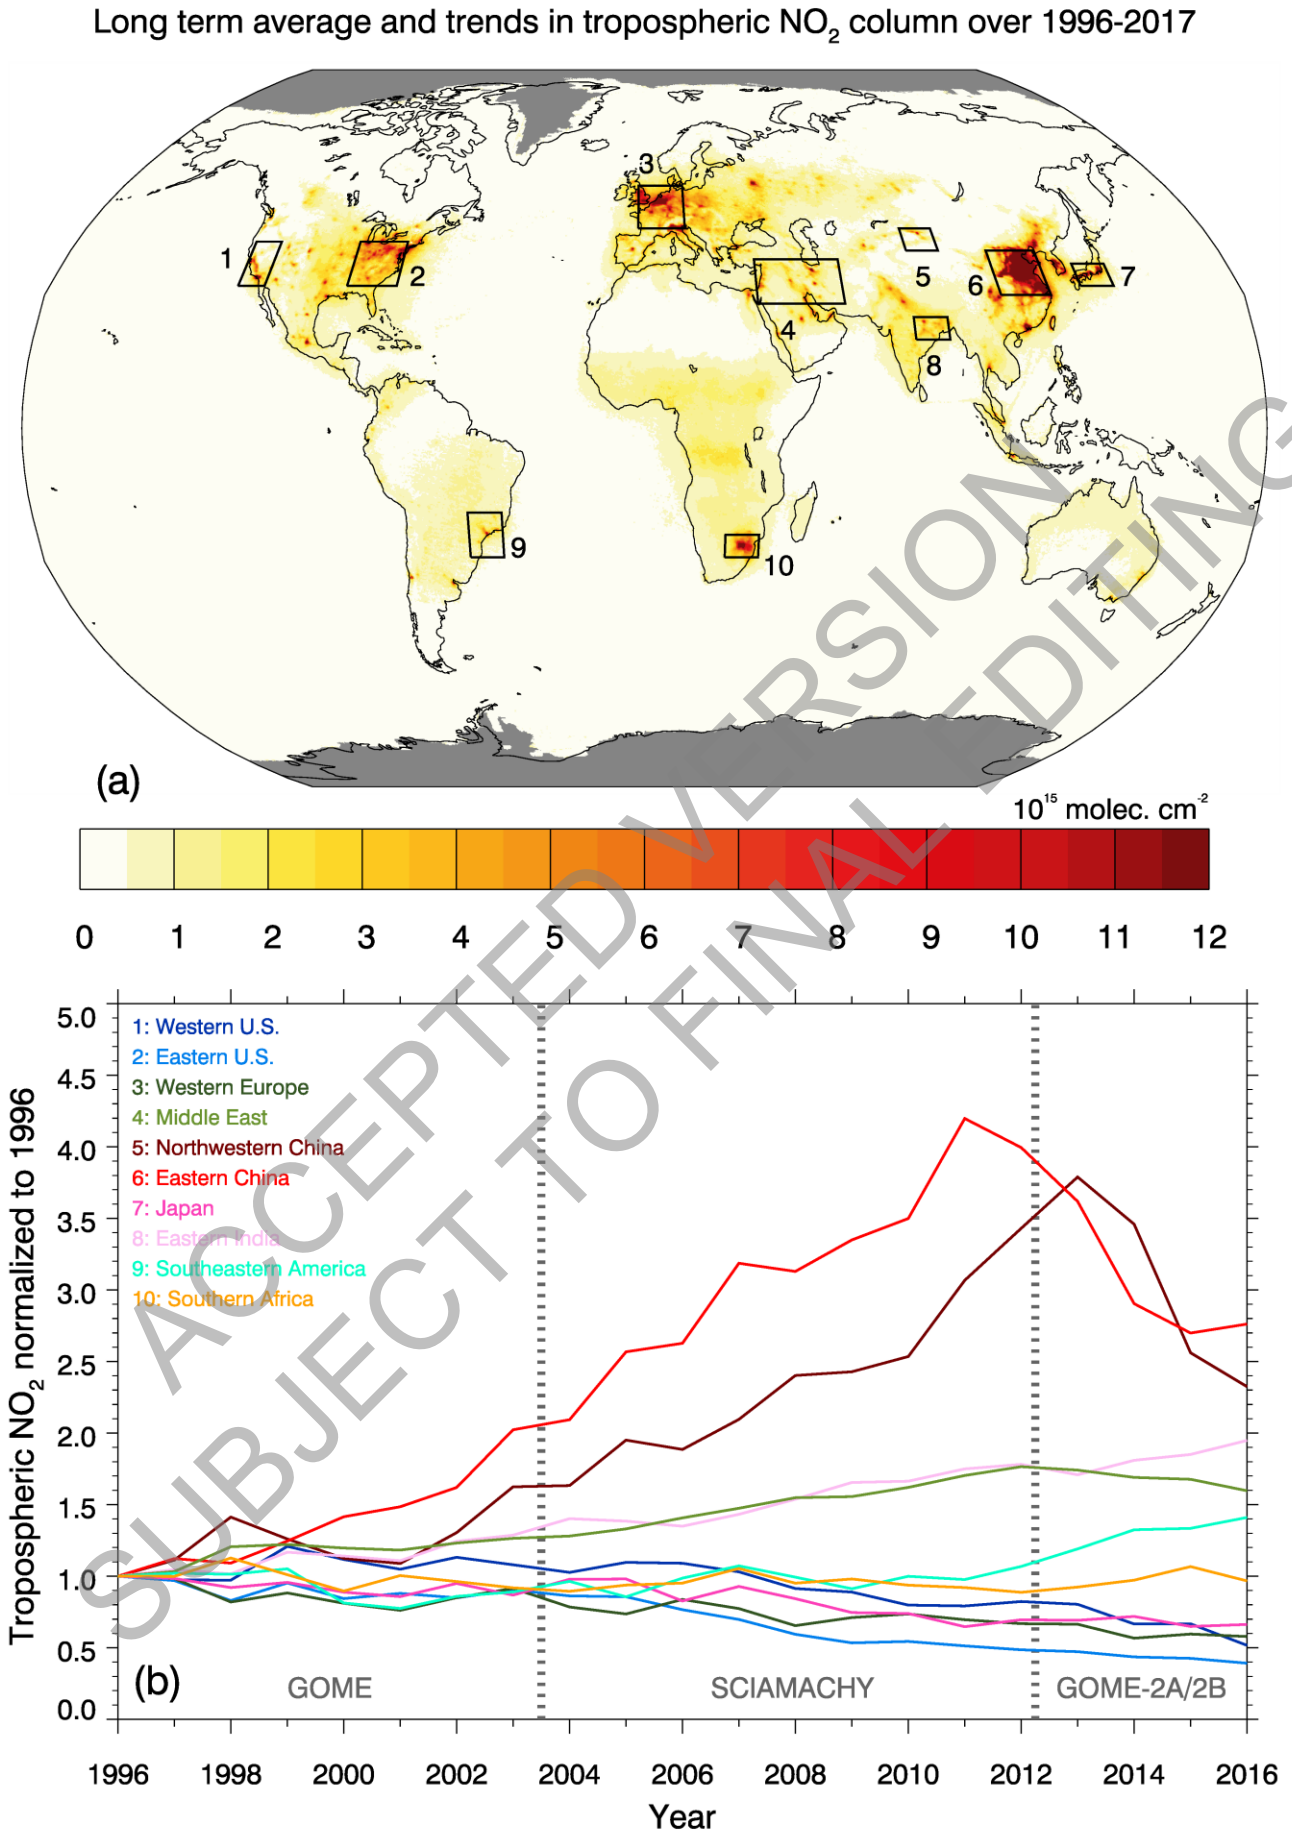


Figure 6.5: Decadal tropospheric ozone trends since 1994. Trends are shown at 28 remote and regionally representative surface sites (Cooper et al., 2020) and in 11 regions of the lower free troposphere (650 hPa, ca. 3.5 km) as measured by In-Service Aircraft for a Global Observing System (IAGOS) above Europe, northeastern USA, southeastern USA, western North America, northeast China, South East Asia, southern India, Persian Gulf, Malaysia/Indonesia, Gulf of Guinea and northern South America (Gaudel et al., 2020). High elevation surface sites are >1500 m above sea level. All trends end with the most recently available year but begin in 1995 or 1994. The sites and datasets are the same as those used in Figure 2.8, further details on data sources and processing are available in the Chapter 2 data table (Table 2.SM.1).

Figure 6.10: Multi-model mean Effective radiative forcings (ERFs) due to aerosol changes between 1850 and recent-past (1995-2014). Panel (a) shows the spatial distribution of the net ERF with area-weighted global mean ERF shown at the lower right corner. Uncertainty is represented using the advanced approach: No overlay indicates regions with robust signal, where ≥66% of models show change greater than variability threshold and ≥80% of all models agree on sign of change; diagonal lines indicate regions with no change or no robust signal, where <66% of models show a change greater than the variability threshold; crossed lines indicate regions with conflicting signal, where ≥66% of models show change

greater than variability threshold and <80% of all models agree on sign of change. For more information on the advanced approach, please refer to the Cross-Chapter Box Atlas.1. Panel (b) shows the mean shortwave and longwave ERF for each of the 14 regions defined in the Atlas. Violins in panel (b) show the distribution of values over regions where ERFs are significant. ERFs are derived from the difference between top of the atmosphere (TOA) radiative fluxes for Aerosol Chemistry Model Intercomparison Project (AerChemMIP) experiments *histSST* and *histSST-piAer* (Collins et al., 2017) averaged over 1995-2014 (Box 1.4, Chapter 1). The results come from 7 Earth System Models: MIROC6, MPI-I-ESM-1-2-HAM, MRI-ESM2-0, GFDL-ESM4, GISS-E2-1-G, NorESM2-LM, and UKESM-0-LL. These data can be seen in the Interactive Atlas. Further details on data sources and processing are available in the chapter data table (Table 6.SM.1).

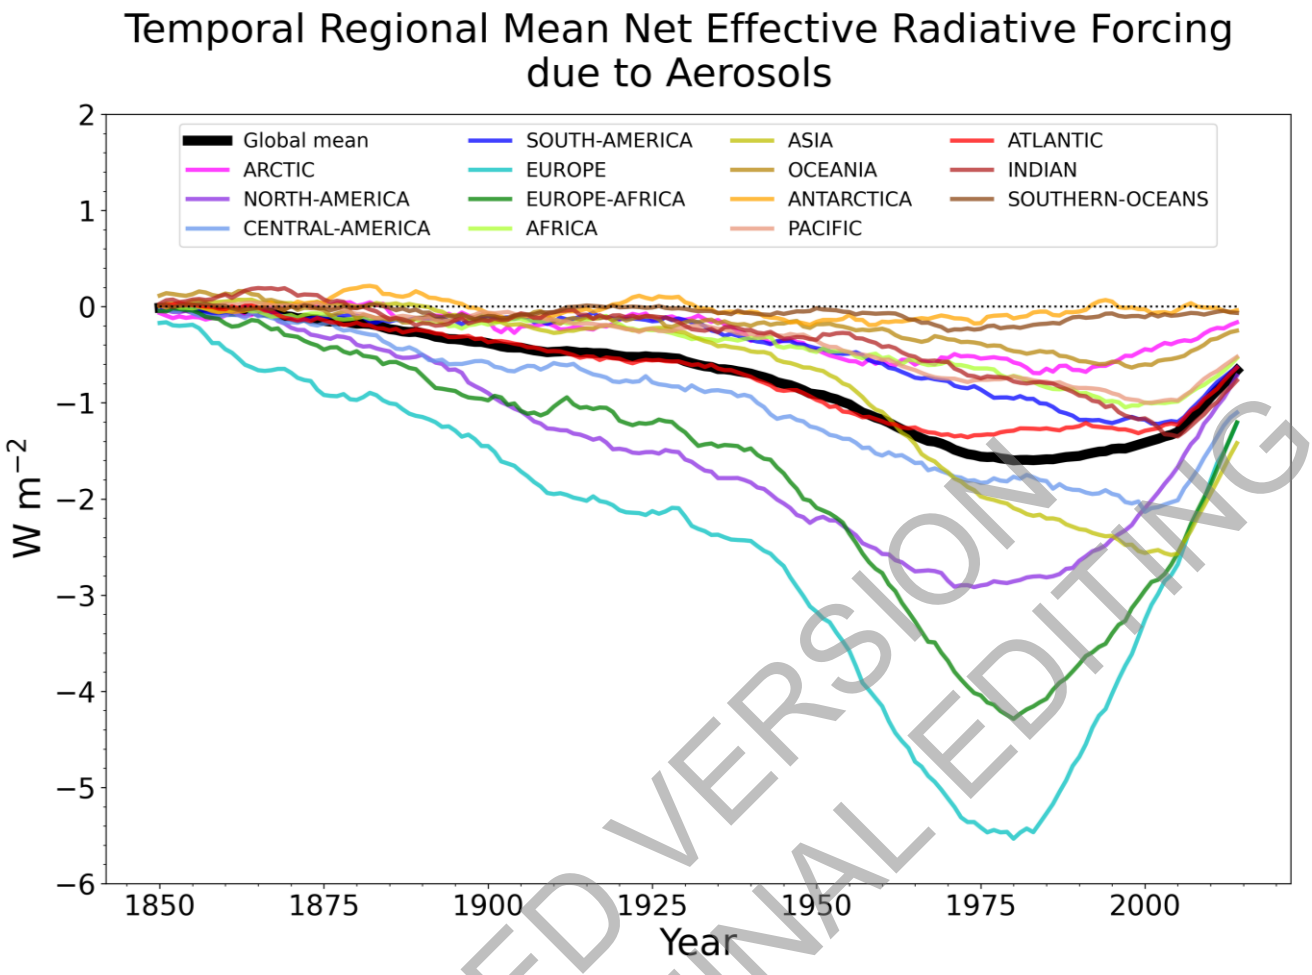

Figure 6.11: Time evolution of 20-year multi-model mean averages of the annual area-weighted mean regional net Effective Radiative Forcings (ERFs) due to aerosols for each of the 14 major regions in the Atlas, and global mean, using the models and model experiments as in Figure 6.10. Further details on data sources and processing are available in the chapter data table (Table 6.SM.1).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

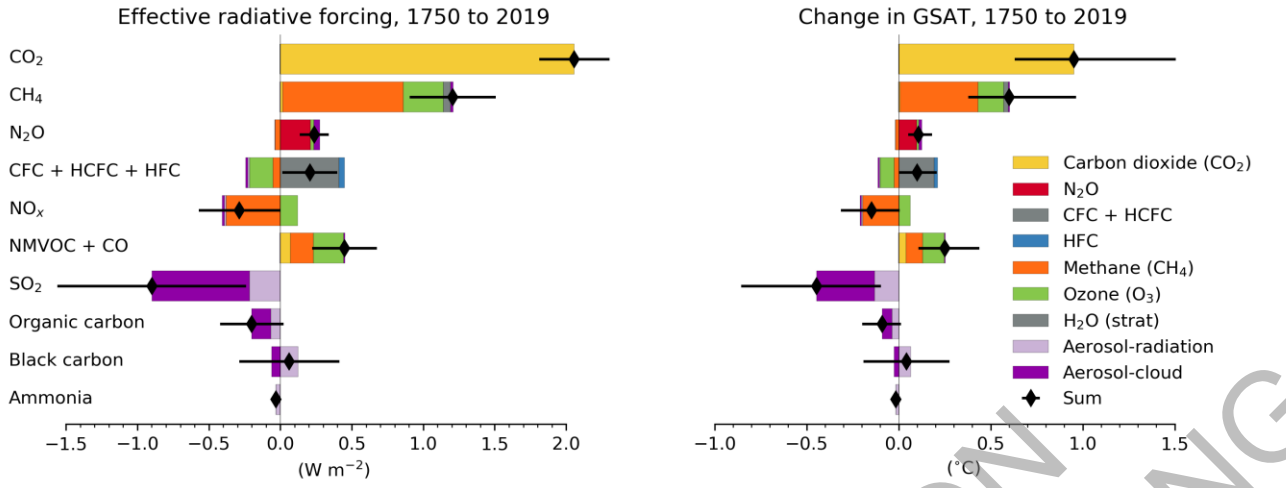

Figure 6.12: Contribution to effective radiative forcing (ERF) (left) and global mean surface air temperature (GSAT) change (right) from component emissions between 1750 to 2019 based on CMIP6 models (Thornhill et al., 2021). ERFs for the direct effect of well-mixed greenhouse gases (WMGHGs) are from the analytical formulae in section 7.3.2, H_2O (strat) is from Table 7.8. ERF for other components are multi-model means from Thornhill et al. (2021) and are based on ESM simulations in which emissions of one species at a time are increased from 1850 to 2014 levels. The derived emission-based ERFs are rescaled to match the concentration-based ERFs in Figure 7.6. Error bars are 5-95% and for the ERF account for uncertainty in radiative efficiencies and multi-model error in the means. ERF due to aerosol-radiation (ERFari) and cloud effects are calculated from separate radiation calls for clear-sky and aerosol free conditions (Ghan, 2013; Thornhill et al., 2021). "Cloud" includes cloud adjustments (semi-direct effect) and ERF from indirect aerosol-cloud to -0.22 W m^{-2} for ERFari and -0.84 W m^{-2} interactions (ERFaci). The aerosol components (SO_2, organic carbon, black carbon) are scaled to sum to -0.22 W m^{-2} for ERFari and -0.84 W m^{-2} for "cloud" (section 7.3.3). For GSAT estimates, time series (1750-2019) for the ERFs have been estimated by scaling with concentrations for WMGHGs and with historical emissions for SLCFs. The time variation of ERFaci for aerosols is from Chapter 7. The global mean temperature response is calculated from the ERF time series using an impulse response function (see Cross-Chapter Box 7.1) with a climate feedback parameter of -1.31 W m^{-2} °C^{-1}. Further details on data sources and processing are available in the chapter data table (Table 6.SM.1).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

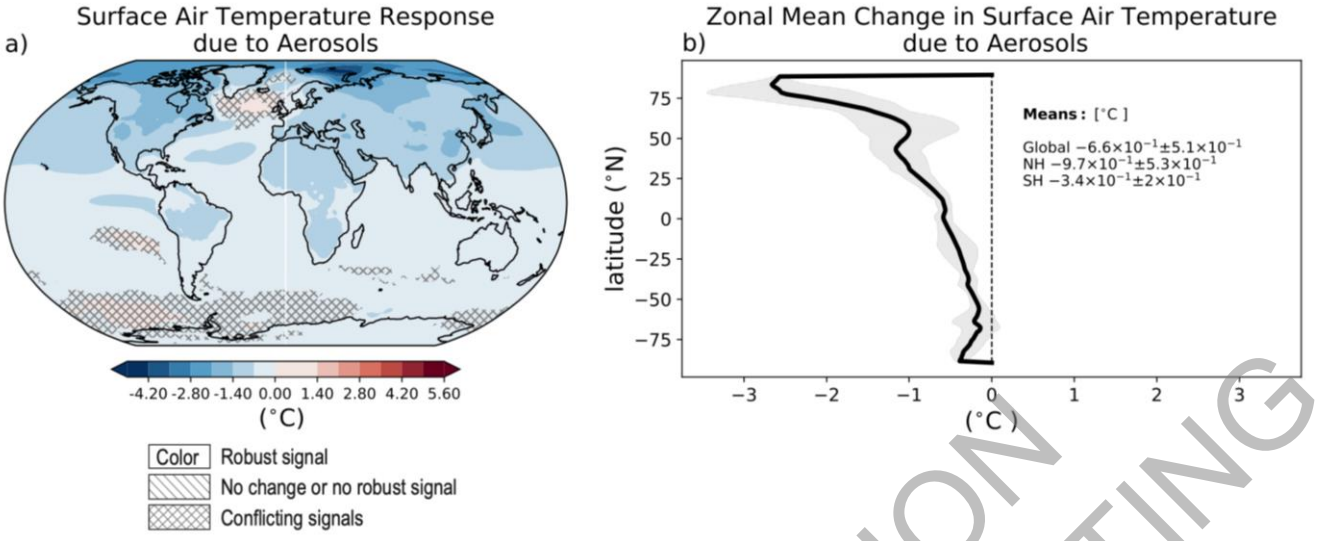

Figure 6.13: Multi-model mean surface air temperature response due to aerosol changes between 1850 and recent-past (1995-2014) calculated as the difference between CMIP6 'historical' and AerChemMIP 'hist-piAer' experiments, where a) is the spatial pattern of the annual mean surface air temperature response, and b) is the mean zonally averaged response. Model means are derived from years 1995-2014. Uncertainty is represented using the advanced approach: No overlay indicates regions with robust signal, where ≥66% of models show change greater than variability threshold and ≥80% of all models agree on sign of change; diagonal lines indicate regions with no change or no robust signal, where <66% of models show a change greater than the variability threshold; crossed lines indicate regions with conflicting signal, where ≥66% of models show change greater than variability threshold and <80% of all models agree on sign of change. For more information on the advanced approach, please refer to the Cross-Chapter Box Atlas.1. AerChemMIP models MIROC6, MRI-ESM2-0, NorESM2-LM, GFDL-ESM4, GISS-E2-1-G, UKESM1-0-LL are used in the analysis. Further details on data sources and processing are available in the chapter data table (Table 6.SM.1).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

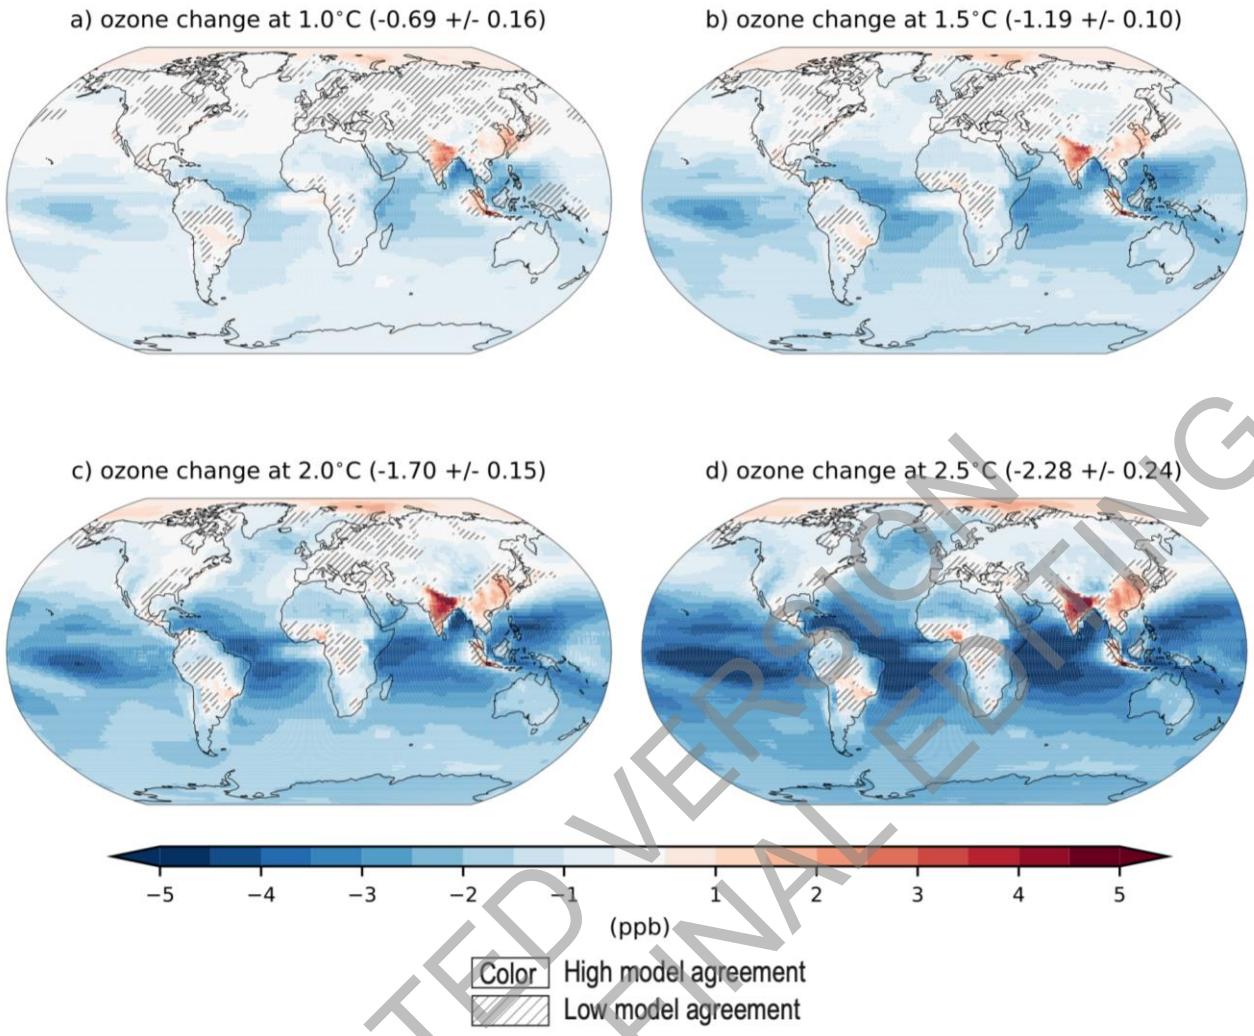

Figure 6.14: Multi-model annual mean change in surface O_3 (ppb) concentrations at different warming levels. Changes are shown for a) 1.0°C, b) 1.5°C, c) 2.0°C and d) 2.5°C increase in global mean surface air temperature. CMIP6 models include GFDL-ESM4, GISS-E2-1-G, MRI-ESM2-0 and UKESM1-0-LL. For each model the change in surface O_3 is calculated as difference between the ssp370SST and ssp370pdSST experiments in the year when the difference in the global mean surface air temperature between the experiments exceeds the temperature threshold. The difference is calculated as a 20-year mean in surface O_3 around the year when the temperature threshold in each model is exceeded. The multi-model change in global annual mean surface O_3 concentrations with ± 1 σ are shown within parenthesis. Uncertainty is represented using the simple approach: No overlay indicates regions with high model agreement, 3 out of 4 models agree on sign of change; diagonal lines indicate regions with low model agreement, where 3 out of 4 models agree on sign of change. For more information on the simple approach, please refer to the Cross-Chapter Box Atlas.1. Further details on data sources and processing are available in the chapter data table (Table 6.SM.1).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

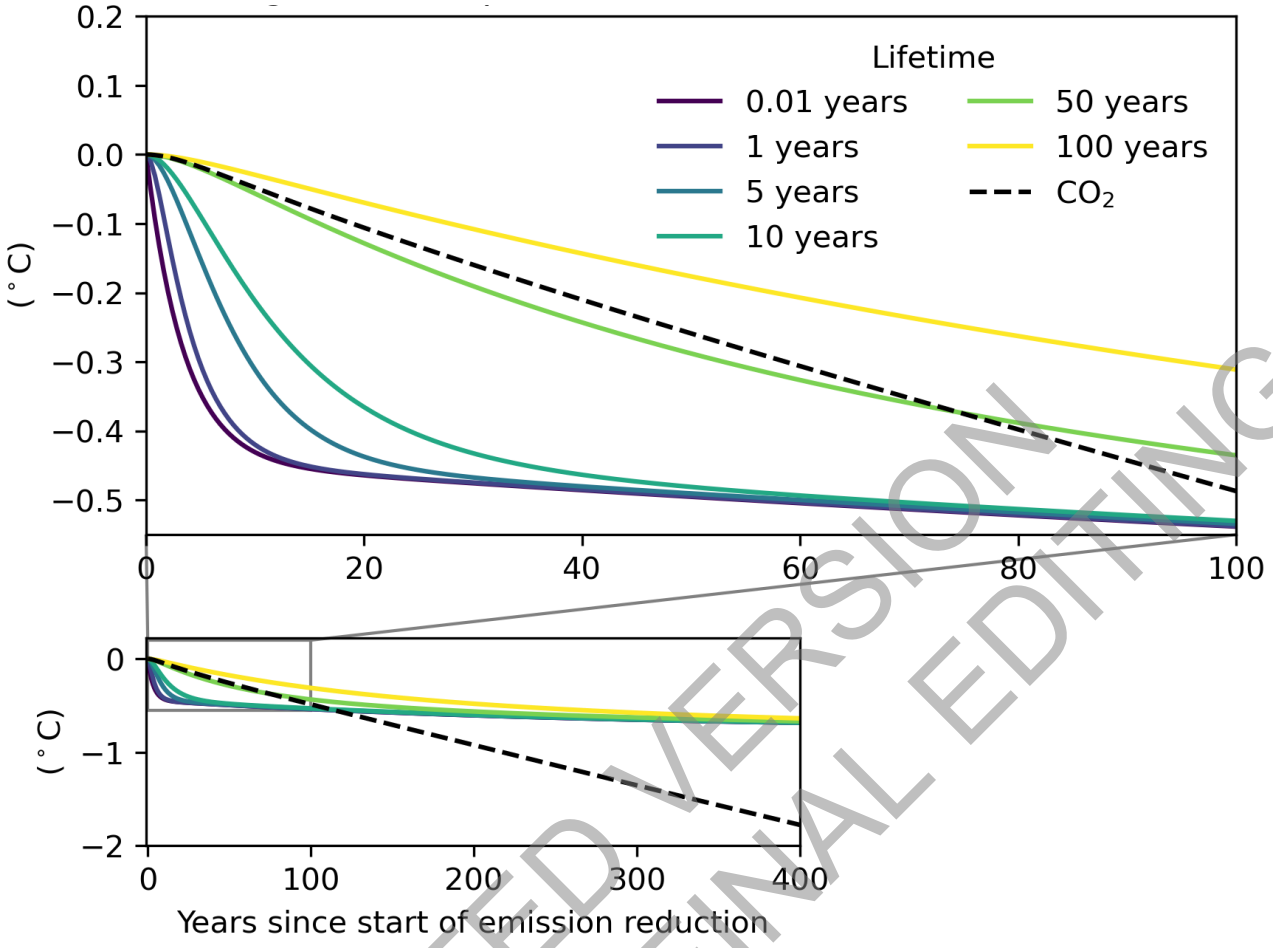

Figure 6.15: Global mean surface air temperature (GSAT) response to an abrupt reduction in emissions (at time t=0) of idealized climate forcing agents with different lifetimes. All emissions are cut to give a radiative forcing of -1 W m^{-2} at steady state (except for CO_2). In other words, if the yearly emissions are E_0 before the reduction, they will have a fixed lower value $E_{year>0} = (E_0 - \Delta E)$ for all succeeding years. For comparison, the GSAT response to a sustained reduction in CO_2 emissions resulting in an RF of -1 W m^{-2} in year 100 is included (dashed line). The temperature response is calculated using an impulse response function (see Cross-Chapter Box 7.1) with a climate feedback parameter of -1.31 W m^{-2} $°C^{-1}$. Further details on data sources and processing are available in the chapter data table (Table 6.SM.1).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

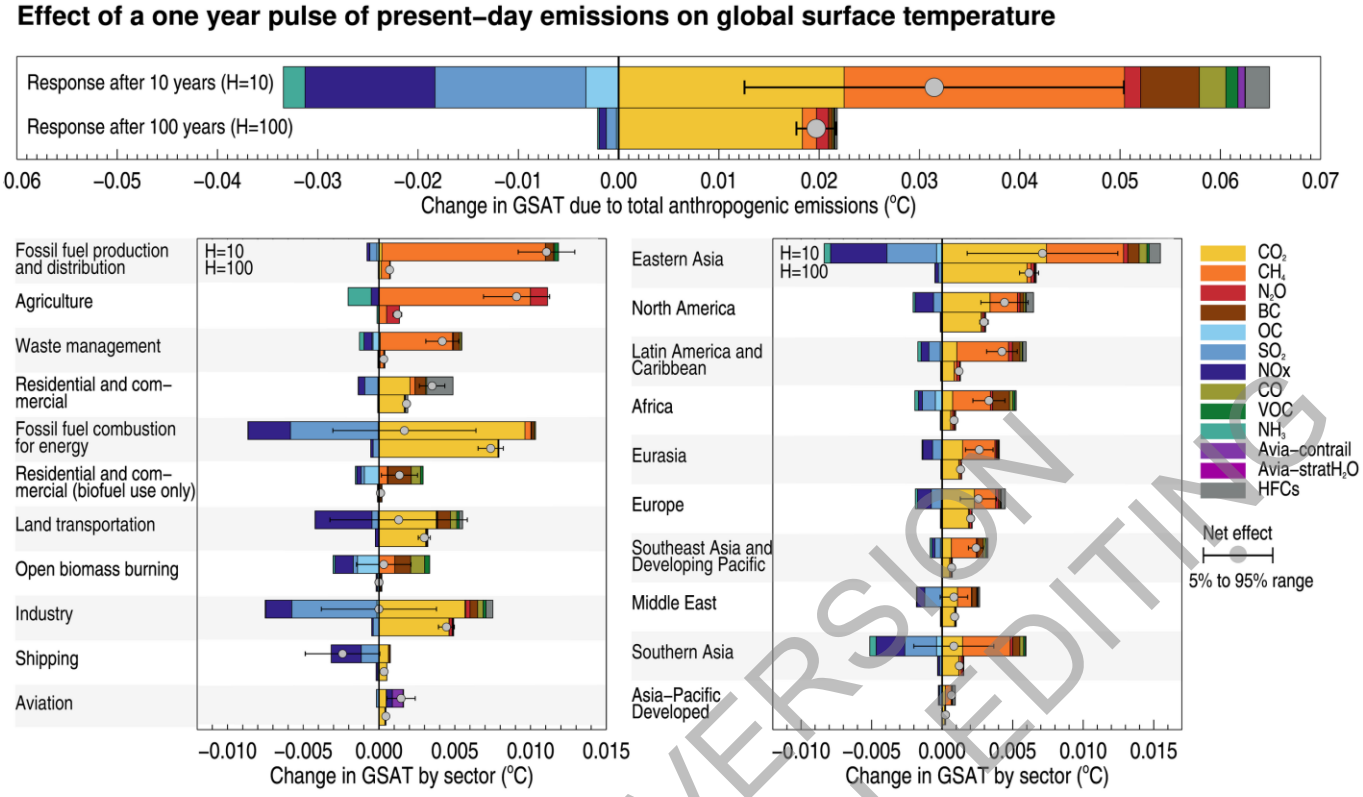

Figure 6.16: Global-mean temperature response 10 and 100 years following one year of present-day (year 2014) emissions. The temperature response is broken down by individual species and shown for total anthropogenic emissions (top), sectoral emissions (left) and regional emissions (right). Sectors and regions are sorted by (high-to-low) net temperature effect on the 10-year time scale. Error bars in the top panel show uncertainty (5-95% interval) in net temperature effect due to uncertainty in radiative forcing *only* (calculated using a Monte Carlo approach and best estimate uncertainties from the literature - see Lund et al. (Lund et al., 2020) for details). CO_2 emissions are excluded from open biomass burning and residential biofuel use due to their unavailability in CEDS and uncertainties around non-sustainable emission fraction. Emissions for 2014 originate from the Community Emissions Data System (CEDS) (Hoesly et al., 2018), except for HFCs which are from Purohit et al. (2020), open biomass burning from van Marle et al. (2017), and aviation H_2O which is from Lee et al.(2020). The split of fossil fuel production and distribution and combustion for energy and residential and commercial fuel use into fossil fuel and biofuel components obtained from the GAINS model (ECLIPSE version 6b dataset). Open biomass burning emissions are not included for the regions. Emission are aggregated into fossil fuel production and distribution (coal mining, oil and gas production, upstream gas flaring, gas distribution networks), agriculture (livestock and crop production), fossil fuel combustion for energy (power plants), industry (combustion and production processes, solvent use losses from production and end use), residential and commercial (fossil fuel use for cooking and heating as well is HFCs leakage from A/C and refrigeration), waste management (solid waste, incl. landfills and open trash burning, residential and industrial waste water), transport (road and off-road vehicles, and HFC leakage from A/C and refrigeration equipment), residential and commercial (biofuels use for cooking and heating), open biomass burning (forest, grassland, savannah fires, and agricultural waste burning), shipping (incl. international shipping), and aviation (incl. international aviation). Further details on data sources and processing are available in the chapter data table (Table 6.SM.1).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

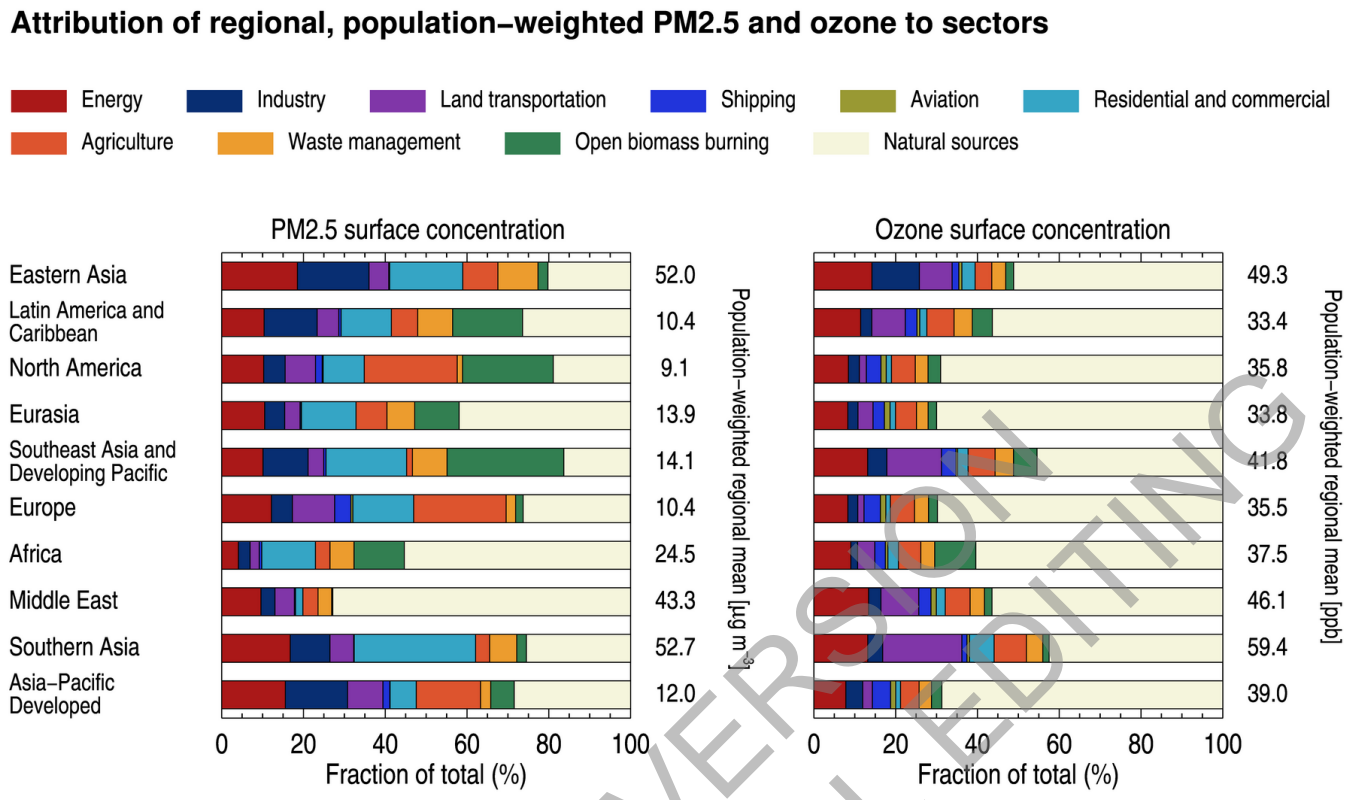

Figure 6.17: Emission source-sector attribution of regional population weighted mean concentrations of $PM_{2.5}$ and ozone for present day emissions (year 2014). Regional concentrations and source apportionment calculated with the TM5-FASST model (Van Dingenen et al., 2018) for the 2014 emission data from the Community Emissions Data System (CEDS) (Hoesly et al., 2018) and van Marle et al.(2017) for open biomass burning. $PM_{2.5}$ dust and seasalt are monthly mean climatological average over 2010-2018 from CAMS global reanalysis (EAC4) (Inness et al., 2019), generated using Copernicus Climate Change Service information [January 2020]. Anthropogenic sectors are similar to those in Figures 6.2 and 6.16 except grouping of fossil fuel production, distribution and combustion for energy under "Energy" and grouping of use of fossil fuel and biofuel use for cooking and heating under "Residential and Commercial". Further details on data sources and processing are available in the chapter data table (Table 6.SM.1).

Figure 6.22: Time evolution of the effects of short-lived climate forcers (SLCFs) and hydrofluorocarbons (HFCs) on global surface air temperature (GSAT) across the WGI core set of Shared Socio-Economic Pathways (SSPs). Effects of net aerosols, methane, tropospheric ozone and hydrofluorocarbons (HFCs) (with lifetimes <50years), and the sum of these, relative to year 2019 and to year 1750. The GSAT changes are based on the assessed historic and future evolution of Effective Radiative Forcing (Section 7.3.5). The temperature responses to the ERFs are calculated with an impulse response function with an equilibrium climate sensitivity of 3.0°C for a doubling of atmospheric CO_2 (feedback parameter of -1.31 W m^{-2} $°C^{-1}$, see CC-Box 7.1). The vertical bars to the right in each panel show the uncertainties (5-95% ranges) for the GSAT change between 2019 and 2100. Further details on data sources and processing are available in the chapter data table (Table 6.SM.1).

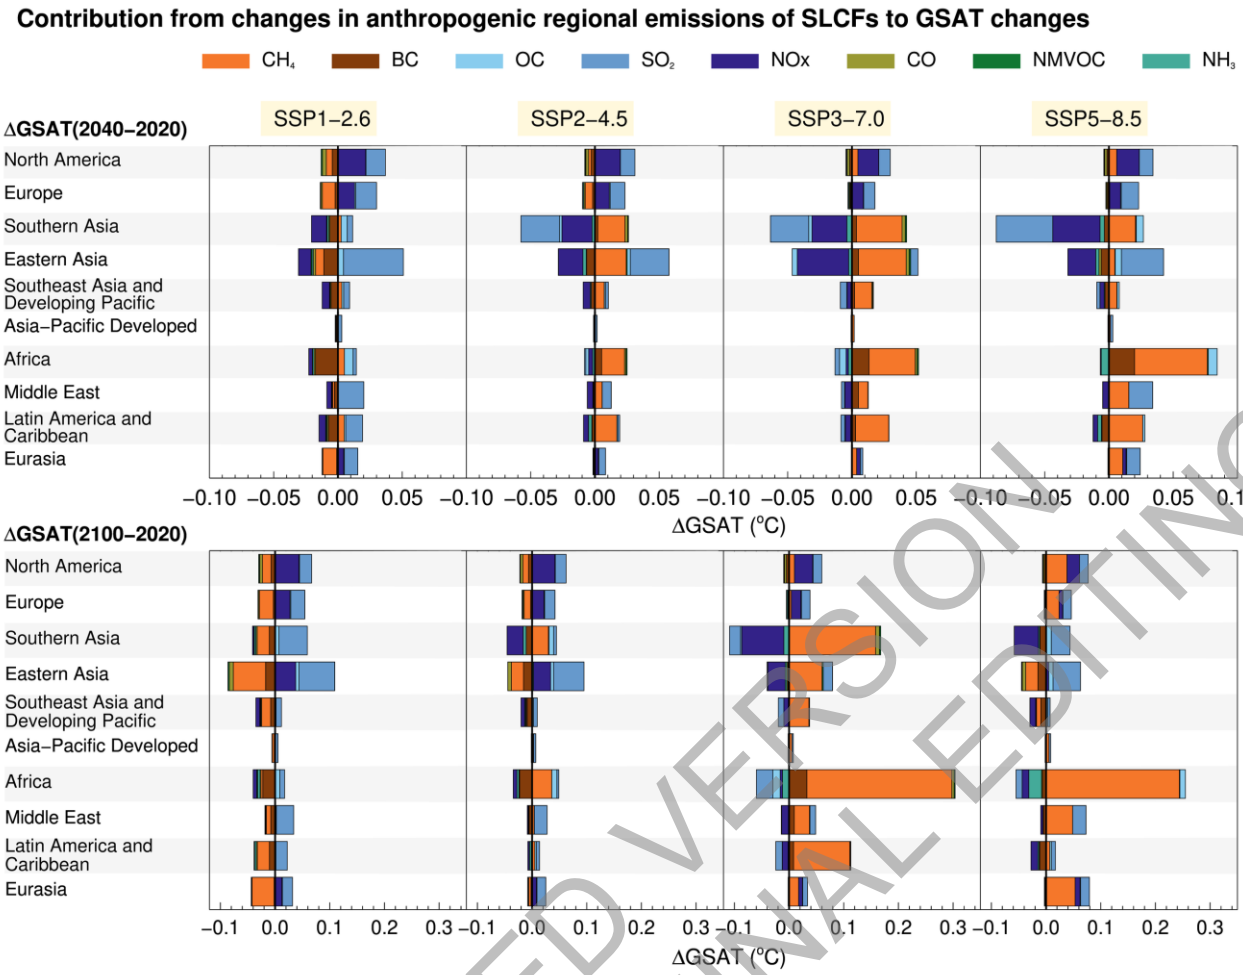

Figure 6.23: Contribution from regional emissions of short-lived climate forcers (SLCFs) to changes in global surface air temperature (GSAT) in 2040 (upper row) and 2100 (lower row), relative to 2020 for four Shared Socio-economic Pathways (SSP). Adapted from (Lund et al., 2020). NO_x, CO, and VOC account for the impact through changes in ozone and methane, NO_x additionally includes the impact through formation of nitrate aerosols. BC, SO_2 and OC accounts for the direct aerosol effect (aerosol-radiation interactions), as well as an estimate of the semi-direct effect for BC due to rapid adjustments and indirect effect (aerosol-cloud interactions) of sulfate aerosols. Regions are the same as shown in the map in Figure 6.7. Further details on data sources and processing are available in the chapter data table (Table 6.SM.1).

Cross-Chapter Box 6.1, Figure 1: **Emission reductions and their effect on aerosols and climate in response to COVID-19.** Estimated reductions in emissions of CO_2, SO_2 and NO_x are shown in panel (a) based on reconstructions using activity data (updated from Forster et al., 2020). Eight Earth System Models (ESMs) performed multiple ensemble simulations of the response to COVID-19 emissions reductions forced with these assumed emission reductions up till August 2020 followed by a constant continuation near the August value to the end of 2020. Emission reductions were applied relative to the SSP2-4.5 scenario. Panel (b) shows ESM simulated AOD at 550nm (only seven models reported this variable). Panel (c) shows ESM simulated GSAT anomalies during 2020; curves denote the ensemble mean result for each model with shading used for ±1 standard deviation for each model. ESM data from these simulations ("ssp245-covid") is archived on the Earth System Grid CMIP6 database. Uncertainty is represented using the simple approach: No overlay indicates regions with high model agreement, where ≥80% of models agree on sign of change; diagonal lines indicate regions with low model agreement, where <80% of models agree on sign of change. For more information on the simple approach, please refer to the Cross-Chapter Box Atlas.1.

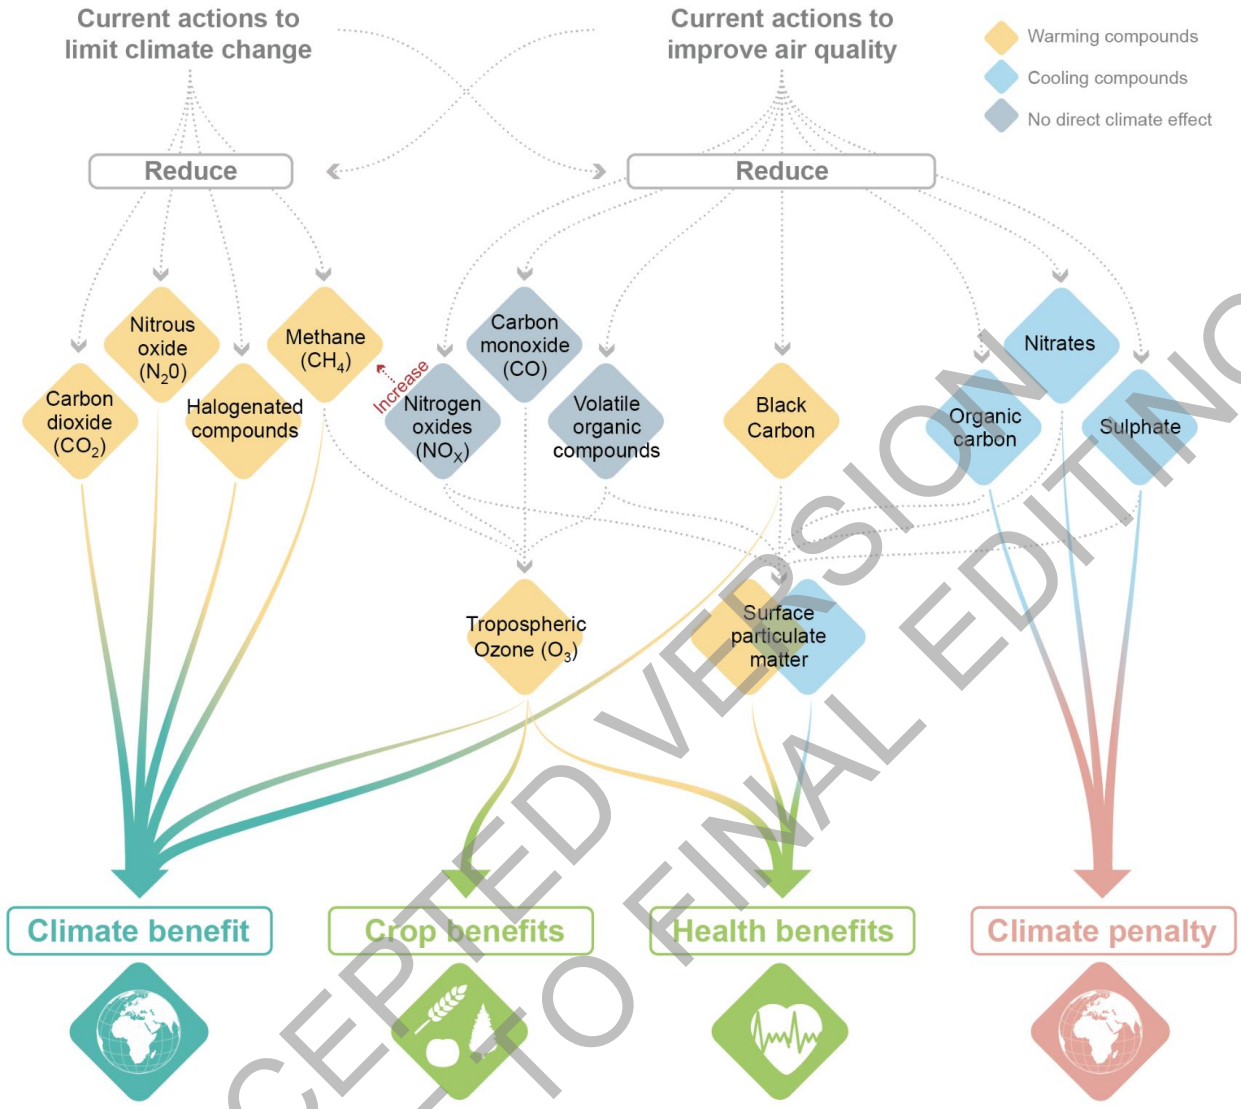
FAQ 6.1: **What are short-lived climate forcers and how do they affect the climate?**

Short lived climate forcers do not remain for very long in the atmosphere, thus an increase or decrease in their emissions rapidly affects the climate system.



FAQ 6.1, Figure 1: Main short-lived climate forcers, their sources, how long they exist in the atmosphere, and their relative contribution to global surface temperature changes between 1750 and 2019 (area of the globe). By definition, this contribution depends on the lifetime, the warming/cooling potential (radiative efficiency), and the emissions of each compound in the atmosphere. Blue indicates cooling and orange warming. Note that, between 1750 and 2019, the cooling contribution from aerosols (blue diamonds and globe) was approximately half the warming contribution from carbon dioxide.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

FAQ 6.2: **Limiting climate change and improving air quality?**

Climate change and air quality are so intimately linked that addressing one issue can affect the other one.

FAQ6.2, Figure 1: Links between actions aiming to limit climate change and actions to improve air quality. Greenhouse gases and aerosols (orange and blue) can affect directly climate. Air pollutants (bottom) can affect the human health, ecosystems and climate. All these compounds have common sources and sometimes interact with each other in the atmosphere which makes impossible to consider them separately (dotted grey arrows).

6.SM.1 Methodology for Emission based ERF

Emission-based ERFs are assessed (Figure 6.12) based on multi-model attribution experiments performed under AerChemMIP (Collins et al., 2017) and analyzed by (Thornhill et al., 2021). The attribution experiments are done with the precursors emissions individually perturbed (except CO and NMVOCs that were done together). Due to the non-linear chemistry and microphysics of the atmosphere, the sum of the emission-based contributions to ERF will not be equal to the concentration-based estimates (Figure 7.6)

The simulations in (Thornhill et al., 2021) are for the 1850-2014, and estimates for the emission-based ERFs have been extrapolated to the full 1750-2019 period based on the updated emission estimates from the 11 September 2020 version of the Community Emissions Data System (CEDS) is used (Hoesly et al., 2018), obtained from https://doi.org/10.5281/zenodo.4025316 (cf 7.SM.1.4)

For the ozone ERF, in the AerChemMIP experiments the methane concentrations have been kept fixed when the individual precursors are perturbed (e.g. NO_x). This means that methane is not governed by its emissions and the atmospheric chemistry. Thus, adjustments have been done to consider the differences between CH_4 concentrations that would have been reached in a free to adjust simulation and a CH_4-fixed simulation. As a consequence of this CH_4 adjustment, a correction has to be applied to all the chemical species which are affected by CH_4 modification, either through chemistry itself (e.g. lifetime) or through stratospheric H_2O changes and cloud changes. Despite these corrections, some non-linear effects in the chemistry can not be fully captured and result in differences between the emission-based radiative forcing and the concentration-based radiative forcing (Figure 7.6 and 7.SM.1.4). So finally, only the proportion of the individual effect is kept from this methodology and applied to the concentration-based ERF which has been determined in a way that allow to consider all the non-linearities.

The emission based ERF estimates for aerosols and aerosol precursors are based on the AerChemMIP simulations (Thornhill et al., 2021). The contribution from aerosol radiation interaction (ari) is calculated as the difference between the total ERF and ERFaci. Thus, the non-cloud adjustments are included as aerosol radiation interaction. For NH_3 emissions ERFaci was not available, the ERF is contributed only to aerosol radiation interaction. As for the ozone precursors, only the proportion of the individual effect is kept from this methodology and applied to the concentration-based ERF .

For CO_2 the fraction of CO_2 in the atmosphere originating from anthropogenic emissions of non-CO_2 emissions must be subtracted from the concentration based estimate. The sum of Carbon emissions over the historical period of CH_4, halocarbons, NMVOC + CO is estimated to be 6.6, 0.02, 26 Gt(C) respectively. This includes a rough assumption that 25%, 0%, 50%, 0% (CH_4, halocarbons, NMVOC, CO) of reactive intermediates such as formaldehyde are lost to deposition. Also assumes that 12% of methane C is still in the atmosphere as methane (Stevenson et al., 2013). Using the (Joos et al., 2013) CO_2 response function to convolve the time profile of emissions gives a rise in CO_2 of 110 ppb that is proportionally subtracted from the CO_2 total.
For the halogenated species, the ERFs for CFCs and HCFCs are taken from Thornhill et al. (2021), and adjusted to include emissions up to 2019. The ERF from HFCs, taken from the concentration-based estimates (7.SM.1.4) are added, neglecting small effects through changes in OH concentrations affecting HFC lifetime.

6.SM.2 ERF and GSAT timeseries from emulators for individual compounds over the historical period

GSAT change in response to ERF from SLCFs has been estimated using an emulator (see cross chapter box 7.1 and 7.SM.2) and presented in Figures 6.12, 6.15, 6.22 and 6.24. The emulator used is an impulse response function (IRF) based on the two-layer energy balance model.
When the ERF time series is known, the response in GSAT at time *t* is given by:

$$GSAT(t) = \int_{t'=0}^{t} ERF(t') \cdot IRF(t - t')dt'$$

Where t'=0 denotes the time when the emission perturbation started, e.g. anthropogenic emissions since 1750.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

The IRF used here has been calibrated according to the procedure given in 7.SM.2, and is given by:

$$IRF(t) = \sum_{j=1}^{J} \frac{c_j}{d_j} \exp\left(-\frac{t}{d_j}\right)$$

where the parameters c_j determine the equilibrium climate response and d_j are timescales of the fast and slow modes of the climate system response, and J=2 here. The parameter values are: d_1 = 3.4 years and d_2 = 285 years, c_1 = 0.44 K/(W m^{-2}) and c_2 = 0.32 K/(W m^{-2}), corresponding to an ECS of 3.0K.

Figure 6.12 shows the historical emission based contributions to GSAT (1750-2019). For this analysis the emission based ERF time series are based on the AerChemMIP simulations (Thornhill et al., 2021), and described in 6.SM.1 and 7.SM.1.4. The emission-based assessment of ERF (6.SM.1) provides ERFs for 2019 relative to 1750, and to establish the ERF time series over the whole historical period, these were scaled back according the historic emissions, i.e. assuming a liner relation between emissions and ERF historically.

Figure 6.15 shows the GSAT response to step emission reductions of idealized climate forcers with different lifetimes. All forcers are assumed to give an ERF of -1.0 Wm^{-2} when a new equilibrium concentration is reached. With this assumption the ERF(t) is given by:

$$ERF(t) = -1.0\, Wm^{-2} \cdot (1 - e^{-\frac{t}{\tau}})$$

Where τ is the atmospheric lifetime of the climate forcer.

Figure 6.22 and 6.24 show the contributions to GSAT from individual SLCFs, or groups of SLCFs, with an abundance-based perspective. The ERF time series are from the assessment of chapter 7 of this report and details are given in 7.SM.1.4.

6.SM.4 Effect on GSAT of a one year pulse of present-day emissions after 20 and 100 years.

[START FIGURE 6.SM.3 HERE]

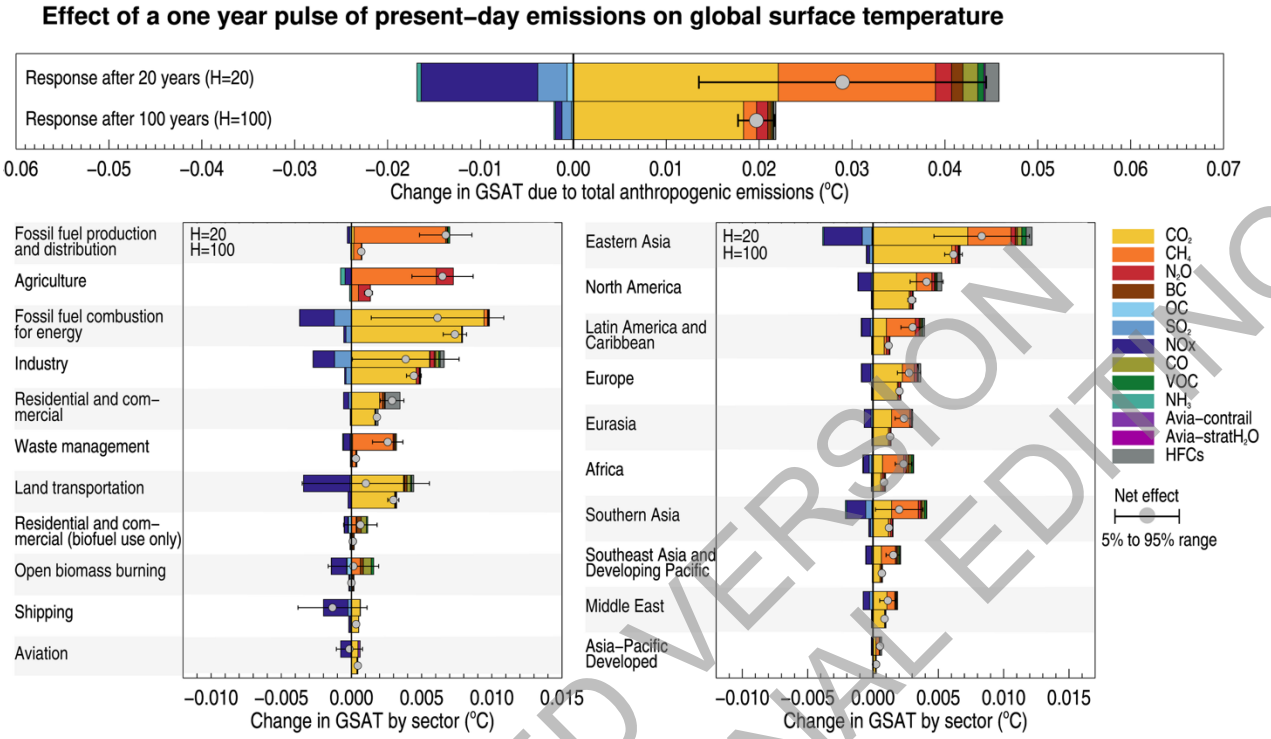

Figure 6.SM.3: Global-mean temperature response 20 and 100 years following one year of present-day (year 2014) emissions.

[END FIGURE 6.SM.3 HERE]

The temperature responses in Figure 6.16 and 6.SM.3 were calculated using the concept of absolute global temperature change potential (AGTP) (Shine et al., 2005), i.e., an emission-metric-based emulator of the climate response to individual emitted species. The approach and further details are documented in Lund et al. (2020). The emissions were taken from the Community Emissions Data System (CEDS) for year 2014 (Hoesly et al., 2018), with the exceptions of HFCs, which originate from Purohit et al. (2020) and consider HFCs with a lifetime shorter than 50 years, open biomass burning from van Marle et al. (2017), and aviation water vapour from Lee et al. (2020). The split between fossil fuel and biofuel emissions in the residential sector, and between the fossil fuel production and distribution and combustion in the energy sector, is based on the GAINS model (ECLIPSE version 6b dataset: https://iiasa.ac.at/web/home/research/researchPrograms/air/Global_emissions.html). CO_2 emissions are excluded from open biomass burning and residential biofuel use due to their unavailability in CEDS and uncertainties around non-sustainable emission fraction.

Aviation specific AGTPs have been calculated for Figure 6.SM.3 using the method described in Lund et al. (2020) and the best estimate radiative forcing values from Lee et al. (2020). For the HFCs , the AGTPs were derived from Hodnebrog et al. (2020). The AGTPs of BC, SO_2 and OC account for the direct aerosol effect due to aerosol-radiation interactions and are scaled to account for the semi-direct of BC due to rapid adjustments and indirect radiative forcing through aerosol-cloud interactions of sulfate aerosols, respectively. All AGTPs used in the temperature response calculations now include a carbon-climate feedback term based on the framework by Gasser et al. (2017), except those for HFCs. Avia-contrail refers to the impact from linear contrail formation and subsequent spreading to cirrus clouds and Avia-stratH_2O to the direct impact of aircraft water vapour emissions.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

The error bars show the range (5-95% interval) in net temperature impact due to uncertainty in radiative forcing *only*. This uncertainty range is calculated using a Monte Carlo approach and estimates of uncertainties in global-mean RF of individual species from the literature - see Lund et al. (2020) for details. The uncertainty in the RF of individual halocarbons was not included due to lack of available data.

The AGTP applies an impulse response function (IRF) to calculate the temperature response as a function of time to a given forcing. The IRF is given by:

$$IRF(t) = \sum_{j=1}^{J} \frac{c_j}{d_j} \exp\left(-\frac{t}{d_j}\right)$$

where c_j and d_j are constants and timescales of the fast and slow model of the climate system response, respectively, and j=2 here. The IRF used in Lund et al. (2020) is based on Geoffroy et al. (2013), which yields d_1 = 4.1 years and d_2 = 249 years, c_1 = 0.519 K/(Wm^{-2}) and c_2 = 0.365 K/(Wm^{-2}), corresponding to an ECS of 3.5K. Note that the IRF used for calculations of GSAT for figures 6.12, 6.15, 6.22 and 6.24 use an IRF calibrated to the assessment of ECS and TCR as given in Chapter 7 of this report, and thus use slightly different values for the c_j and d_j constants (see 6.SM.2).

6.SM.5 Methodology to compute source sector apportionment for surface air pollutants using TM5-FASST

Here we provide description of the methodology used to calculate the source sector apportionment for $PM_{2.5}$ and ozone (Figure 6.17). Furthermore, Figures 6.SM4 and 6.SM.5 show a comparison of TM5-FASST and ESM models responses to changes in emissions of $PM_{2.5}$ precursors and ozone.

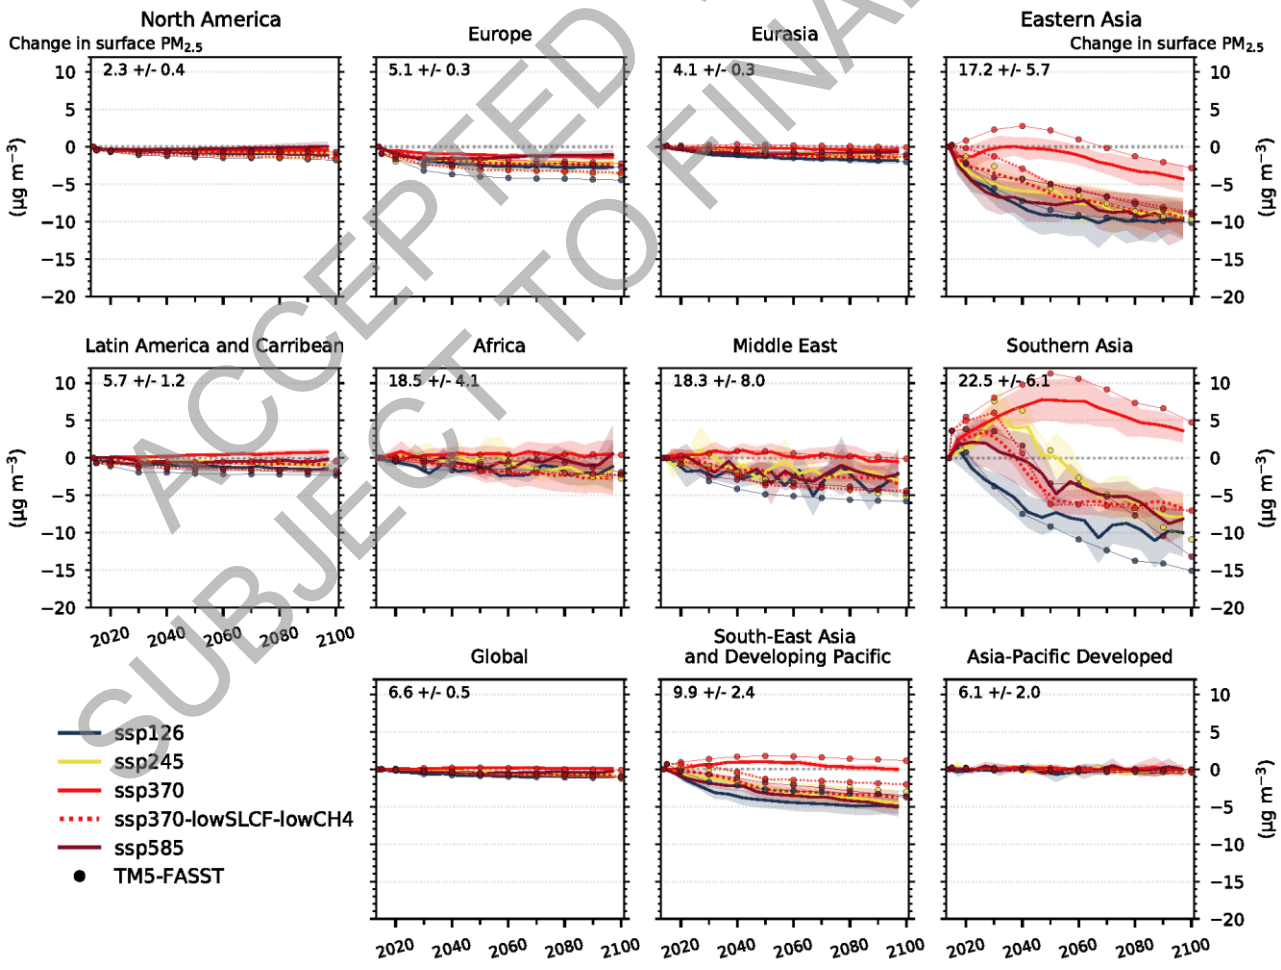
TM5-FASST is a reduced-form source-receptor model, describing the surface level spatial response of a pollutant metric (concentration, exposure, deposition) to changes in precursor emissions. The model is constructed from pre-computed emission-concentration transfer matrices between pollutant source regions and receptor regions. These matrices reflect underlying meteorological and chemical atmospheric processes for a predefined set of meteorological and emission data and have the advantage that concentration responses to emission changes are obtained by a simple matrix multiplication, avoiding expensive numerical computations.

TM5-FASST's source-receptor matrices have been derived with the chemistry-transport model TM5, by applying 20% emission perturbations on a reference emission set (RCP year 2000, year 2001 meteorology) for individual precursors and 56 source regions. The total concentration of component (or metric) *j* in receptor region *y*, resulting from given emissions *E* of *all* n_i precursors *i* at *all* n_x source regions *x*, is obtained as a perturbation on the base-simulation concentration, by summing up all the respective source-receptor coefficients A, scaled with the actual emission perturbation:

$$C_j(y) = C_{j,\mathrm{ref}}(y) + \sum_{k=1}^{n_x} \sum_{i=1}^{n_i} A_{ij}[x_k, y] \cdot \left[E_i(x_k) - E_{i,\mathrm{ref}}(x_k)\right] \quad (1)$$

where $A_{ij}[x_k, y] = \frac{\Delta C_{j,ref}(y)}{0.2 E_{i,\mathrm{ref}}(x_k)}$, the pre-computed source-receptor coefficient for source region x_k to receptor region *y*, for precursor i contributing to metric/pollutant j. The computational efficiency from the linearized emission-concentration sensitivities comes at some cost of accuracy, in particular because the model bypasses underlying mechanisms describing chemical and meteorological feedback processes that could lead to non-linear responses.

TM5-FASST computes $PM_{2.5}$ concentrations from precursor emissions of SO_2, NO_x, NH_3, elemental carbon and particulate organic matter. Secondary organic matter from anthropogenic emissions is not included. Ozone concentrations and long-term exposure metrics are computed from NO_x, non-methane volatile organic compounds (NMVOC) and methane precursor emissions. CO as ozone precursor is not included. The methane-ozone response is assumed to be instantaneous, neglecting the 11 year response time (Fiore et al.,



ACCEPTED VERSION SUBJECT TO FINAL EDITING

2008)

The computational efficiency of TM5-FASST allows for multiple runs exploring source attribution by region or emission source. We estimate the relative contribution of individual emission sectors shown in Figure 6.17 by subtracting their emissions one by one from the total emissions in Eq. (1) and computing the resulting concentration. Subtracting this result from the total concentration (Eq. 1) yields each sector's contribution (Karagulian et al., 2016).

TM5-FASST has been extensively documented and evaluated by (Van Dingenen et al., 2018). The model has been applied in a variety of assessment studies (e.g., Aakre et al., 2018; Brauer et al., 2016; Crippa et al., 2019; Harmsen et al., 2020; Kühn et al., 2020; Markandya et al., 2018; Rao et al., 2017; Rauner et al., 2020; Vandyck et al., 2020). Validation studies in Van Dingenen et al. (2018) show that, despite inherent simplifications and caveats, large scale $PM_{2.5}$ and O_3 responses to emission changes in TM5-FASST compare well with the chemical transport model TM5. Figure 6.SM.4 and 6.SM.5 compare TM5-FASST regional $PM_{2.5}$ and O_3 responses to emission changes with the ensemble of ESM models for selected SSP scenarios. In nearly all cases TM5-FASST results fall within ±1 standard deviation of the CMIP6 ESM ensemble. Notable differences are observed for the SSP scenarios and regions representing more extreme emission changes (in particular for the low emission scenarios in Southern Asia). As documented by Van Dingenen et al. (2018), both for $PM_{2.5}$ and O_3 the differences with full process models can be attributed to non-linear responses to NO_x emission reductions that are not captured by the linearized source-receptor model.

Executive Summary

This chapter assesses the present state of knowledge of Earth's energy budget, that is, the main flows of energy into and out of the Earth system, and how these energy flows govern the climate response to a radiative forcing. Changes in atmospheric composition and land use, like those caused by anthropogenic greenhouse gas emissions and emissions of aerosols and their precursors, affect climate through perturbations to Earth's top-of-atmosphere energy budget. The effective radiative forcings (ERFs) quantify these perturbations, including any consequent adjustment to the climate system (but excluding surface temperature response). How the climate system responds to a given forcing is determined by climate feedbacks associated with physical, biogeophysical and biogeochemical processes. These feedback processes are assessed, as are useful measures of global climate response, namely equilibrium climate sensitivity (ECS) and the transient climate response (TCR). This chapter also assesses emission metrics, which are used to quantify how the climate response due to the emission of different greenhouse gases compares to the response to the emission of carbon dioxide (CO_2). This chapter builds on the assessment of carbon cycle and aerosol processes from Chapters 5 and 6, respectively, to quantify non-CO_2 biogeochemical feedbacks and the ERF for aerosols. Chapters 3, 4, 5, 6 and 9 use the assessment of ERF, ECS and TCR from this chapter to help understand historical and future temperature changes, the response to cumulative emissions, the remaining carbon budget and sea level rise respectively. This chapter builds on findings from the IPCC Fifth Assessment Report (AR5), the Special Report on Global Warming of 1.5°C (SR1.5), the Special Report on Ocean and Cryosphere in a Changing Climate (SROCC) and the Special Report on Climate Change and Land (SRCCL). *Very likely* ranges are presented unless otherwise indicated.

Earth's Energy Budget

Since AR5, the accumulation of energy in the Earth system, quantified by changes in the global energy inventory for all components of the climate system, has become established as a robust measure of the rate of global climate change on interannual-to-decadal timescales. Compared to changes in global surface air temperature (GSAT), the global energy inventory exhibits less variability, which can mask underlying climate trends. Compared to AR5, there is increased confidence in the quantification of changes in the global energy inventory due to improved observational records and closure of the sea level budget. Energy will continue to accumulate in the Earth system until at least the end of the 21st century, even under strong mitigation scenarios, and will primarily be manifest through ocean warming and associated with continued sea level rise through thermal expansion. (*high confidence*) {7.2.2, Box 7.2, Table 7.1, Chapter 9 Cross-Chapter Box 9.1, Table 9.5, 9.2.2, 9.6.3}

The global energy inventory increased by 435 [325 to 545] Zettajoules (ZJ) for the period 1971–2018 and 153 [101 to 206] ZJ for the period 2006–2018. This corresponds to an Earth energy imbalance of 0.57 [0.43 to 0.72] W m^{-2} for the period 1971–2018, increasing to 0.79 [0.52 to 1.06] W m^{-2} for the period 2006–2018, expressed per unit area of Earth's surface. Ocean heat uptake is by far the largest contribution and accounts for 91% of the total energy change. Compared to AR5, the contribution from land heating has been revised upwards from about 3% to about 5%. Melting of ice and warming of the atmosphere account for about 3% and 1% of the total change respectively. More comprehensive analysis of inventory components and cross-validation of satellite and in situ-based global heating rates lead to a more confident assessment relative to AR5. (*high confidence*) {Box 7.2, 7.2.2, Table 7.1, 7.5.2.3}

Improved quantification of effective radiative forcing, the climate system radiative response, and the observed energy increase in the Earth system for the period 1971–2018 demonstrate improved closure of the global energy budget compared to AR5. Combining the *likely* range of ERF with the central estimate of radiative response gives an expected energy gain of 340 [47 to 662] ZJ. Combining the *likely* range of climate response with the central estimate of ERF gives an expected energy gain of 340 [147 to 527] ZJ. Both estimates are consistent with an independent observation-based assessment of the global energy increase of 284 [96 to 471] ZJ, (*very likely range*) expressed relative to the estimated 1850-1900 Earth energy imbalance. (*high confidence*) {7.2.2, Box 7.2, 7.3.5, 7.5.2}

Since AR5, additional evidence for a widespread decline (or dimming) in solar radiation reaching the

ACCEPTED VERSION SUBJECT TO FINAL EDITING

surface is found in the observational records between the 1950s and 1980s, with a partial recovery (brightening) at many observational sites thereafter (*high confidence*). These trends are neither a local phenomenon nor a measurement artefact (*high confidence*). Multi-decadal variation in anthropogenic aerosol emissions are thought to be a major contributor (*medium confidence*), but multi-decadal variability in cloudiness may also have played a role. The downward and upward thermal radiation at the surface has increased in recent decades, in line with increased greenhouse gas concentrations and associated surface and atmospheric warming and moistening (*medium confidence*). {7.2.2}

Effective Radiative Forcing

For carbon dioxide, methane, nitrous oxide and chlorofluorocarbons, there is now evidence to quantify the effect on ERF of tropospheric adjustments (e.g., from changes in atmospheric temperatures, clouds and water vapour). The assessed ERF for a doubling of carbon dioxide compared to 1750 levels (3.93 ± 0.47 W m^{-2}) is larger than in AR5. Effective radiative forcings (ERF), introduced in AR5, have been estimated for a larger number of agents and shown to be more closely related to the temperature response than the stratospheric-temperature adjusted radiative forcing. For carbon dioxide, the adjustments include the physiological effects on vegetation. (*high confidence*) {7.3.2}

The total anthropogenic ERF over the industrial era (1750–2019) was 2.72 [1.96 to 3.48] W m^{-2}. This estimate has increased by 0.43 W m^{-2} compared to AR5 estimates for 1750–2011. This increase includes a +0.34 W m^{-2} from increases in atmospheric concentrations of well-mixed greenhouse gases (including halogenated species) since 2011, a +0.15 W m^{-2} from upwards revisions of their radiative efficiencies and a +0.10 W m^{-2} from re-evaluation of the ozone and stratospheric water vapour ERF. The 0.59 W m^{-2} increase in ERF from greenhouse gases is partly offset by a better-constrained assessment of total aerosol ERF that is more strongly negative than in AR5, based on multiple lines of evidence (*high confidence*). Changes in surface reflectance from land-use change, deposition of light-absorbing particles on ice and snow, and contrails and aviation-induced cirrus have also contributed to the total anthropogenic ERF over the industrial era, with –0.20 [–0.30 to –0.10] W m^{-2} (*medium confidence*), +0.08 [0 to 0.18] W m^{-2} (*low confidence*) and +0.06 [0.02 to 0.10] W m^{-2} (*low confidence*), respectively. {7.3.2, 7.3.4, 7.3.5}

Anthropogenic emissions of greenhouse gases (GHGs) and their precursors contribute an ERF of 3.84 [3.46 to 4.22] W m^{-2} over the industrial era (1750–2019). Most of this total ERF, 3.32 [3.03 to 3.61] W m^{-2}, comes from the well-mixed greenhouse gases, with changes in ozone and stratospheric water vapour (from methane oxidation) contributing the remainder. The ERF of GHGs is composed of 2.16 [1.90 to 2.41] W m^{-2} from carbon dioxide, 0.54 [0.43 to 0.65] W m^{-2} from methane, 0.41 [0.33 to 0.49] W m^{-2} from halogenated species, and 0.21 [0.18 to 0.24] W m^{-2} from nitrous oxide. The ERF for ozone is 0.47 [0.24 to 0.71] W m^{-2}. The estimate of ERF for ozone has increased since AR5 due to revised estimates of precursor emissions and better accounting for effects of tropospheric ozone precursors in the stratosphere. The estimated ERF for methane has slightly increased due to a combination of increases from improved spectroscopic treatments being somewhat offset by accounting for adjustments. (*high confidence*) {7.3.2, 7.3.5}

Aerosols contribute an ERF of –1.3 [–2.0 to –0.6] W m^{-2} over the industrial era (1750–2014) (*medium confidence*). The ERF due to aerosol–cloud interactions (ERFaci) contributes most to the magnitude of the total aerosol ERF (*high confidence*) and is assessed to be –1.0 [–1.7 to –0.3] W m^{-2} (*medium confidence*), with the remainder due to aerosol–radiation interactions (ERFari), assessed to be –0.3 [–0.6 to 0.0] W m^{-2} (*medium confidence*). There has been an increase in the estimated magnitude but a reduction in the uncertainty of the total aerosol ERF relative to AR5, supported by a combination of increased process-understanding and progress in modelling and observational analyses. ERF estimates from these separate lines of evidence are now consistent with each other, in contrast to AR5, and support the assessment that it is *virtually certain* that the total aerosol ERF is negative. Compared to AR5, the assessed magnitude of ERFaci has increased, while the magnitude of ERFari has decreased. The total aerosol ERF over the period 1750–2019 is less certain than the headline statement assessment. It is also assessed to be smaller in magnitude at –1.1 [–1.7 to –0.4] W m^{-2}, primarily due to recent emission changes (*medium confidence*). {7.3.3, 7.3.5, 2.2.6}

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Climate Feedbacks and Sensitivity

The net effect of changes in clouds in response to global warming is to amplify human-induced warming, that is, the net cloud feedback is positive (*high confidence*). Compared to AR5, major advances in the understanding of cloud processes have increased the level of confidence and decreased the uncertainty range in the cloud feedback by about 50%. An assessment of the low-altitude cloud feedback over the subtropical oceans, which was previously the major source of uncertainty in the net cloud feedback, is improved owing to a combined use of climate model simulations, satellite observations, and explicit simulations of clouds, altogether leading to strong evidence that this type of cloud amplifies global warming. The net cloud feedback, obtained by summing the cloud feedbacks assessed for individual regimes, is 0.42 [–0.10 to 0.94] W m^{-2} $°C^{-1}$. A net negative cloud feedback is *very unlikely*. (*high confidence*) {7.4.2, Figure 7.10, Table 7.10}

The combined effect of all known radiative feedbacks (physical, biogeophysical, and non-CO_2 biogeochemical) is to amplify the base climate response, also known as the Planck temperature response (*virtually certain*). Combining these feedbacks with the base climate response, the net feedback parameter based on process understanding is assessed to be –1.16 [–1.81 to –0.51] W m^{-2} $°C^{-1}$, which is slightly less negative than that inferred from the overall ECS assessment. The combined water vapour and lapse rate feedback makes the largest single contribution to global warming, whereas the cloud feedback remains the largest contribution to overall uncertainty. Due to the state-dependence of feedbacks, as evidenced from paleoclimate observations and from models, the net feedback parameter will increase (become less negative) as global temperature increases. Furthermore, on long time scales the ice sheet feedback parameter is *very likely* positive, promoting additional warming on millennial time scales as ice sheets come into equilibrium with the forcing. (*high confidence*) {7.4.2, 7.4.3, 7.5.7}

Radiative feedbacks, particularly from clouds, are expected to become less negative (more amplifying) on multi-decadal timescales as the *spatial pattern* of surface warming evolves, leading to an ECS that is higher than was inferred in AR5 based on warming over the instrumental record. This new understanding, along with updated estimates of historical temperature change, ERF, and Earth's energy imbalance, reconciles previously disparate ECS estimates (*high confidence*). However, there is currently insufficient evidence to quantify a *likely* range of the magnitude of future changes to current climate feedbacks. Warming over the instrumental record provides robust constraints on the lower end of the ECS range (*high confidence*), but owing to the possibility of future feedback changes it does not, on its own, constrain the upper end of the range, in contrast to what was reported in AR5. {7.4.4, 7.5.2, 7.5.3}

Based on multiple lines of evidence the best estimate of ECS is 3°C, the *likely* range is 2.5°C to 4°C, and the *very likely* range is 2°C to 5°C. It is *virtually certain* that ECS is larger than 1.5°C. Substantial advances since AR5 have been made in quantifying ECS based on feedback process understanding, the instrumental record, paleoclimates and emergent constraints. There is a high level of agreement among the different lines of evidence. All lines of evidence help rule out ECS values below 1.5°C, but currently it is not possible to rule out ECS values above 5 °C. Therefore, the 5°C upper end of the *very likely* range is assessed to have *medium confidence* and the other bounds have *high confidence*. {7.5.5}

Based on process understanding, warming over the instrumental record, and emergent constraints, the best estimate of TCR is 1.8°C, the *likely* range is 1.4°C to 2.2°C and the *very likely* range is 1.2°C to 2.4°C (*high confidence*). {7.5.5}

On average, CMIP6 models have higher mean ECS and TCR values than the CMIP5 generation of models. They also have higher mean values and wider spreads than the assessed best estimates and *very likely* ranges within this Report. These higher ECS and TCR values can, in some models, be traced to changes in extra-tropical cloud feedbacks that have emerged from efforts to reduce biases in these clouds compared to satellite observations (*medium confidence*). The broader ECS and TCR ranges from CMIP6 also lead the models to project a range of future warming that is wider than the assessed warming range, which is based on multiple lines of evidence. However, some of the high-sensitivity CMIP6 models are less consistent

ACCEPTED VERSION SUBJECT TO FINAL EDITING

with observed recent changes in global warming and with paleoclimate proxy data than models with ECS within the *very likely* range. Similarly, some of the low-sensitivity models are less consistent with the paleoclimate data. The CMIP models with the highest ECS and TCR values provide insights into high-risk, low-likelihood futures, which cannot be excluded based on currently-available evidence. (*high confidence*) {4.3.1, 4.3.4, 7.4.2, 7.5.6}

Climate Response

The total human-forced GSAT change from 1750–2019 is calculated to be 1.29 [0.99 to 1.65] °C. This calculation is an emulator-based estimate, constrained by the historic GSAT and ocean heat content changes from Chapter 2 and the ERF, ECS and TCR from this chapter. The calculated GSAT change is composed of a well-mixed greenhouse gas warming of 1.58 [1.17 to 2.17] °C (*high confidence*), a warming from ozone changes of 0.23 [0.11 to 0.39] °C (*high confidence*), a cooling of –0.50 [–0.22 to –0.96] °C from aerosol effects (*medium confidence*), and a –0.06 [–0.15 to +0.01] °C contribution from surface reflectance changes from land-use change and light absorbing particles on ice and snow (*medium confidence*). Changes in solar and volcanic activity are assessed to have together contributed a small change of –0.02 [–0.06 to +0.02] °C since 1750 (*medium confidence*). {7.3.5}

Uncertainties regarding the true value of ECS and TCR are the dominant source of uncertainty in global temperature projections over the 21st century under moderate to high GHG emission scenarios. For scenarios that reach net zero carbon dioxide emissions, the uncertainty in the ERF values of aerosol and other short-lived forcings contribute substantial uncertainty in projected temperature. Global ocean heat uptake is a smaller source of uncertainty in centennial-time-scale surface warming. (*high confidence*) {7.5.7}

The assessed historical and future ranges of GSAT change in this Report are shown to be internally consistent with the Report's assessment of key physical-climate indicators: greenhouse gas ERFs, ECS and TCR. When calibrated to match the assessed ranges within the assessment, physically based emulators can reproduce the best estimate of GSAT change over 1850–1900 to 1995–2014 to within 5% and the *very likely* range of this GSAT change to within 10%. Two physically based emulators match at least two-thirds of the Chapter 4-assessed projected GSAT changes to within these levels of precision. When used for multi-scenario experiments, calibrated physically based emulators can adequately reflect assessments regarding future GSAT from Earth system models and/or other lines of evidence. (*high confidence*) {Cross-Chapter Box 7.1}

It is now well understood that the Arctic warms more quickly than the Antarctic due to differences in radiative feedbacks and ocean heat uptake between the poles, but that surface warming will eventually be amplified in both poles (*high confidence*). The causes of this polar amplification are well understood, and the evidence is stronger than at the time of AR5, supported by better agreement between modelled and observed polar amplification during warm paleo time periods (*high confidence*). The Antarctic warms more slowly than the Arctic owing primarily to upwelling in the Southern Ocean, and even at equilibrium is expected to warm less than the Arctic. The rate of Arctic surface warming will continue to exceed the global average over this century (*high confidence*). There is also *high confidence* that Antarctic amplification will emerge as the Southern Ocean surface warms on centennial time scales, although only *low confidence* regarding whether the feature will emerge during the 21st century. {7.4.4}

The assessed global warming potentials (GWP) and global temperature-change potentials (GTP) for methane and nitrous oxide are slightly lower than in AR5 due to revised estimates of their lifetimes and updated estimates of their indirect chemical effects (*medium confidence*). The assessed metrics now also include the carbon-cycle response for non-CO_2 gases. The carbon cycle estimate is lower than in AR5, but there is *high confidence* in the need for its inclusion and in the quantification methodology. Metrics for methane from fossil fuel sources account for the extra fossil CO_2 that these emissions contribute to the atmosphere and so have slightly higher emission metric values than those from biogenic sources (*high confidence*). {7.6.1}

ACCEPTED VERSION SUBJECT TO FINAL EDITING

New emission metric approaches such as GWP* and the combined-GTP (CGTP) are designed to relate emission rates of short-lived gases to cumulative emissions of CO_2. These metric approaches are well suited to estimate the GSAT response from aggregated emissions of a range of gases over time, which can be done by scaling the cumulative CO_2 equivalent emissions calculated with these metrics by the transient climate response to cumulative emissions of carbon dioxide. For a given multi-gas emission pathway, the estimated contribution of emissions to surface warming is improved by either using these new metric approaches or by treating short- and long-lived GHG emission pathways separately, as compared to approaches that aggregate emissions of GHGs using standard GWP or GTP emission metrics. By contrast, if emissions are weighted by their 100-year GWP or GTP values, different multi-gas emission pathways with the same aggregated CO_2 equivalent emissions rarely lead to the same estimated temperature outcome. (*high confidence*) {7.6.1, Box 7.3}

The choice of emission metric affects the quantification of net zero GHG emissions and therefore the resulting temperature outcome after net zero emissions are achieved. In general, achieving net zero CO_2 emissions and declining non-CO_2 radiative forcing would be sufficient to prevent additional human-caused warming. Reaching net zero GHG emissions as quantified by GWP-100 typically results in global temperatures that peak and then decline after net zero GHGs emissions are achieved, though this outcome depends on the relative sequencing of mitigation of short-lived and long-lived species. In contrast, reaching net zero GHG emissions when quantified using new emission metrics such as CGTP or GWP* would lead to approximate temperature stabilization (*high confidence*) {7.6.2}

7.1 Introduction, conceptual framework, and advances since AR5

This chapter assesses the major physical processes that affect the evolution of Earth's energy budget and the associated changes in surface temperature and the broader climate system, integrating elements that were dealt with separately in previous reports.

The top-of-atmosphere (TOA) energy budget determines the net amount of energy entering or leaving the climate system. Its time variations can be monitored in three ways, using: (i) satellite observations of the radiative fluxes at the TOA; (ii) observations of the accumulation of energy in the climate system; and (iii) observations of surface energy fluxes. When the TOA energy budget is changed by a human or natural cause (a radiative forcing), the climate system responds by warming or cooling (i.e., the system gains or loses energy). Understanding of changes in the Earth's energy flows helps understanding of the main physical processes driving climate change. It also provides a fundamental test of climate models and their projections.

This chapter principally builds on AR5 (Boucher, 2012; Church et al., 2013; Collins et al., 2013a; Flato et al., 2013; Hartmann et al., 2013; Myhre et al., 2013b; Rhein et al., 2013). It also builds on the subsequent SR1.5 (IPCC, 2018), SROCC (IPCC, 2019a) and SRCCL (IPCC, 2019b), as well as community-led assessments (e.g., Bellouin et al. (2019) covering aerosol radiative forcing and Sherwood et al. (2020) covering equilibrium climate sensitivity).

Throughout this chapter, global surface air temperature (GSAT) is used to quantify surface temperature change (see Cross-Chapter Box 2.3, Chapter 4 Section 4.3.4). The total energy accumulation in the Earth system represents a metric of global change that is complementary to GSAT but shows considerably less variability on interannual-to-decadal timescales (Section 7.2.2). Research and new observations since AR5 have improved scientific confidence in the quantification of changes in the global energy inventory and corresponding estimates of Earth's energy imbalance (Section 7.2). Improved understanding of adjustments to radiative forcing and of aerosol-cloud interactions have led to revisions of forcing estimates (Section 7.3). New approaches to the quantification and treatment of feedbacks (Section 7.4) have improved the understanding of their nature and time-evolution, leading to a better understanding of how these feedbacks relate to Equilibrium Climate Sensitivity (ECS). This has helped to reconcile disparate estimates of ECS from different lines of evidence (Section 7.5). Innovations in the use of emission metrics have clarified the relationships between metric choice and temperature policy goals (Section 7.6), linking this chapter to WGIII which provides further information on metrics, their use, and policy goals beyond temperature. *Very likely* (5% to 95%) ranges are presented unless otherwise indicated. In particular, the addition of (one standard deviation) indicates that the range represents one standard deviation.

In Box 7.1 an energy budget framework is introduced, which forms the basis for the discussions and scientific assessment in the remainder of this chapter and across the report. The framework reflects advances in the understanding of the Earth system response to climate forcing since the publication of AR5. A schematic of this framework and the key changes relative to the science reported in AR5 are provided in Figure 7.1.

[START FIGURE 7.1 HERE]

Figure 7.1: A visual abstract of the chapter, illustrating why the Earth's energy budget matters and how it relates to the underlying chapter assessment. The methods used to assess processes and key new findings relative to AR5 are highlighted.

[END FIGURE 7.1 HERE]

A simple way to characterise the behaviour of multiple aspects of the climate system at once is to summarise them using global-scale metrics. This report distinguishes between "climate metrics" (e.g., ECS, TCR) and "emission metrics" (such as the global warming potential; GWP, or global temperature potential; GTP), but

ACCEPTED VERSION SUBJECT TO FINAL EDITING

this distinction is not definitive. Climate metrics are generally used to summarise aspects of the surface temperature response (Box 7.1). Emission metrics are generally used to summarise the relative effects of emissions of different forcing agents, usually greenhouse gases (see Section 7.6). The climate metrics used in this report typically evaluate how the Earth system response varies with atmospheric gas concentration or change in radiative forcing. Emission metrics evaluate how radiative forcing or a key climate variable (such as GSAT) is affected by the emissions of a certain amount of gas. Emission-related metrics are sometimes used in mitigation policy decisions such as trading greenhouse gas reduction measures and life cycle analysis. Climate metrics are useful to gauge the range of future climate impacts for adaptation decisions under a given emission pathway. Metrics such as the transient climate response to cumulative emissions of carbon dioxide (TCRE) are used in both adaptation and mitigation contexts: for gauging future global surface temperature change under specific emission scenarios, and to estimate remaining carbon budgets that are used to inform mitigation policies (see Chapter 5, Section 5.5).

Given that TCR and ECS are metrics of GSAT response to a theoretical doubling of atmospheric CO_2 (Box 7.1), they do not directly correspond to the warming that would occur under realistic forcing scenarios that include time-varying CO_2 concentrations and non-CO_2 forcing agents (such as aerosols and land-use changes). It has been argued that TCR, as a metric of transient warming, is more policy-relevant than ECS (Frame et al., 2006; Schwartz, 2018). However, as detailed in Chapter 4, both established and recent results (Forster et al., 2013; Gregory et al., 2015; Marotzke and Forster, 2015; Grose et al., 2018; Marotzke, 2019) indicate that TCR and ECS help explain variation across climate models both over the historical period and across a range of concentration-driven future scenarios. In emission-driven scenarios the carbon cycle response is also important (Smith et al., 2019). The proportion of variation explained by ECS and TCR varies with scenario and the time period considered, but both past and future surface warming depend on these metrics (Section 7.5.7).

Regional changes in temperature, rainfall, and climate extremes have been found to correlate well with the forced changes in GSAT within Earth System Models (ESMs) (Giorgetta et al., 2013; Tebaldi and Arblaster, 2014; Seneviratne et al., 2016; Chapter 4, Section 4.6.1). While this so-called 'pattern scaling' has important limitations arising from, for instance, localized forcings, land-use changes, or internal climate variability (Deser et al., 2012; Luyssaert et al., 2014), changes in GSAT nonetheless explain a substantial fraction of inter-model differences in projections of regional climate changes over the 21st century (Tebaldi and Knutti, 2018). This Chapter's assessments of TCR and ECS thus provide constraints on future global and regional climate change (Chapter 4 and Chapter 11).

[START BOX 7.1 HERE]

BOX 7.1: The energy budget framework – forcing and response

The forcing and response energy budget framework provides a methodology to assess the effect of individual drivers of global mean surface temperature response, and to facilitate the understanding of the key phenomena that set the magnitude of this temperature response. The framework used here is developed from that adopted in previous IPCC reports (see Ramaswamy et al., 2019 for a discussion). *Effective Radiative Forcing* (ERF), introduced in AR5 (Boucher et al., 2013; Myhre et al., 2013b) is more explicitly defined in this report and is employed as the central definition of radiative forcing (Sherwood et al. 2015, Box 7.1, Figure 1a). The framework has also been extended to allow variations in feedbacks over different timescales and with changing climate state (Section 7.4.4; Section 7.4.3).

The GSAT response to perturbations that give rise to an energy imbalance is traditionally approximated by the following linear energy budget equation, in which ΔN represents the change in the top-of-atmosphere (TOA) net energy flux, ΔF is an ***effective radiative forcing*** perturbation to the TOA net energy flux, α is the net ***feedback parameter*** and ΔT is the change in ***GSAT***:

$$\Delta N = \Delta F + \alpha \Delta T \qquad \text{Box 7.1, Equation (7.1)}$$

ERF is the TOA energy budget change resulting from the perturbation, excluding any radiative response

ACCEPTED VERSION SUBJECT TO FINAL EDITING

related to a change in GSAT (i.e., ΔT =0). Climate feedbacks (α) represent those processes that change the TOA energy budget in response to a given ΔT.

[START BOX 7.1, FIGURE 1 HERE]

Box 7.1, Figure 1: Schematics of the forcing-feedback framework adopted within the assessment, following Equation 7.1. Illustrated is how the Earth's TOA net energy flux might evolve for a hypothetical doubling of atmospheric CO_2 concentration above preindustrial levels, where an initial positive energy imbalance (energy entering the Earth system, shown on the y-axis) is gradually restored towards equilibrium as the surface temperature warms (shown on the x-axis). a) illustrates the definitions of ERF for the special case of a doubling of atmospheric CO_2 concentration, the feedback parameter and the ECS. b) illustrates how approximate estimates of these metrics are made within the chapter and how these approximations might relate to the exact definitions adopted in panel a).

[END BOX 7.1, FIGURE 1 HERE]

The ***effective radiative forcing, ERF*** (ΔF; units: W m^{-2}) quantifies the change in the net TOA energy flux of the Earth system due to an imposed perturbation (e.g., changes in greenhouse gas or aerosol concentrations, in incoming solar radiation, or land-use change). ERF is expressed as a change in net downward radiative flux at the TOA following adjustments in both tropospheric and stratospheric temperatures, water vapour, clouds, and some surface properties, such as surface albedo from vegetation changes, that are uncoupled to any GSAT change (Smith et al., 2018b). These adjustments affect the TOA energy balance and hence the ERF. They are generally assumed to be linear and additive (Section 7.3.1). Accounting for such processes gives an estimate of ERF that is more representative of the climate change response associated with forcing agents than stratospheric-temperature-adjusted radiative forcing (SARF) or the instantaneous radiative forcing (IRF) (Section 7.3.1). Adjustments are processes that are independent of GSAT change, whereas feedbacks refer to processes caused by GSAT change. Although adjustments generally occur on timescales of hours to several months, and feedbacks respond to ocean surface temperature changes on timescales of a year or more, timescale is not used to separate the definitions. ERF has often been approximated as the TOA energy balance change due to an imposed perturbation in climate model simulations with sea-surface temperature and sea-ice concentrations set to their pre-industrial climatological values (e.g., Forster et al., 2016). However, to match the adopted forcing-feedback framework, the small effects of any GSAT change from changes in land surface temperatures need to be removed from the TOA energy balance in such simulations to give an approximate measure of ERF (Box 7.1, Figure 1b and Section 7.3.1).

The ***feedback parameter,*** $\boldsymbol{\alpha}$, (units: W m^{-2} °C^{-1}) quantifies the change in net energy flux at the TOA for a given change in GSAT. Many climate variables affect the TOA energy budget, and the feedback parameter can be decomposed, to first order, into a sum of terms $\alpha = \sum_x \frac{\partial N}{\partial x}\frac{dx}{dT}$], where x represents a variable of the Earth system that has a direct effect on the energy budget at the TOA. The sum of the feedback terms (i.e., α in Equation 7.1) governs Earth's equilibrium GSAT response to an imposed ERF. In previous assessments, α and the related ECS have been associated with a distinct set of physical processes (Planck response and changes in water vapour, lapse rate, surface albedo, and clouds) (Charney et al., 1979). In this assessment, a more general definition of α and ECS is adopted such that they include additional Earth system processes that act across many timescales (e.g., changes in natural aerosol emissions or vegetation). Because, in our assessment, these additional processes sum to a near-zero value, including these additional processes does not change the assessed central value of ECS but does affect its assessed uncertainty range (Section 7.4.2). Note that there is no standardised notation or sign convention for the feedback parameter in the literature. Here the convention is used that the sum of all feedback terms (the net feedback parameter, α) is negative for a stable climate that radiates additional energy to space with a GSAT increase, with a more negative value of α corresponding to a stronger radiative response and thus a smaller GSAT change required to balance a change in ERF (Equation 7.1). A change in process x amplifies the temperature response to a forcing when the associated feedback parameter α_x is positive (positive feedback) and dampens the temperature response

ACCEPTED VERSION SUBJECT TO FINAL EDITING

when α_x is negative (negative feedback). New research since AR5 emphasises how feedbacks can vary over different timescales (Section 7.4.4) and with climate state (Section 7.4.3), giving rise to the concept of an *effective feedback parameter* that may be different from the equilibrium value of the feedback parameter governing ECS (Section 7.4.3).

The ***equilibrium climate sensitivity***, ***ECS*** (units: °C), is defined as the equilibrium value of ΔT in response to a sustained doubling of atmospheric CO_2 concentration from a pre-industrial reference state. The value of ERF for this scenario is denoted by ΔF_{2xCO2}, giving $ECS = -\Delta F_{2xCO2}/\alpha$ from Equation (7.1) applied at equilibrium (see Box 7.1, Figure 1a and Section 7.5). Equilibrium refers to a steady state where ΔN averages to zero over a multi-century period. ECS is representative of the multi-century to millennial ΔT response to ΔF_{2xCO2}, and is based on a CO_2 concentration change so any feedbacks that affect the atmospheric concentration of CO_2 do not influence its value. As employed here, ECS also excludes the long-term response of the ice sheets (Section 7.4.2.6) which may take multiple millennia to reach equilibrium, but includes all other feedbacks. Due to a number of factors, studies rarely estimate ECS or α at equilibrium or under CO_2 forcing alone. Rather, they give an *effective feedback parameter* (Section 7.4.1 and Box 7.1, Figure 1b) or an *effective ECS* (Section 7.5.1 and Box 7.1, Figure 1b), which represent approximations to the true values of α or ECS. The *effective ECS* represents the equilibrium value of ΔT in response to a sustained doubling of atmospheric CO_2 concentration that would occur assuming the *effective feedback parameter* applied at that equilibrium state. For example, a feedback parameter can be estimated from the linear slope of ΔN against ΔT over a set number of years within ESM simulations of an abrupt doubling or quadrupling of atmospheric CO_2 ($2\times CO_2$ or $4\times CO_2$, respectively), and the ECS can be estimated from the intersect of this regression line with $\Delta N = 0$ (see Box 7.1, Figure 1b). To infer ECS from a given estimate of effective ECS necessitates that assumptions are made for how ERF varies with CO_2 concentration (Section 7.3.2) and how the slope of ΔN against ΔT relates to the slope of the straight line from ERF to ECS (see Section 7.5 and Box 7.1, Figure 1b). Care has to be taken when comparing results across different lines of evidence to translate their estimates of the effective ECS into the ECS definition used here (Section 7.5.5).

The ***transient climate response, TCR*** (units: °C), is defined as the ΔT for the hypothetical scenario in which CO_2 increases at 1% yr^{-1} from a pre-industrial reference state to the time of a doubling of atmospheric CO_2 concentration (year 70) (Section 7.5). TCR is based on a CO_2 concentration change, so any feedbacks that affect the atmospheric concentration of CO_2 do not influence its value. It is a measure of transient warming accounting for the strength of climate feedbacks and ocean heat uptake. The ***transient climate response to cumulative emissions of carbon dioxide*** (***TCRE***) is defined as the transient ΔT per 1000 Gt C of cumulative CO_2 emission increase since preindustrial. TCRE combines information on the airborne fraction of cumulative CO_2 emissions (the fraction of the total CO_2 emitted that remains in the atmosphere at the time of doubling, which is determined by carbon cycle processes) with information on the TCR. TCR is assessed in this chapter, whereas TCRE is assessed in Chapter 5, Section 5.5.

[END BOX 7.1 HERE]

7.2 Earth's energy budget and its changes through time

Earth's energy budget encompasses the major energy flows of relevance for the climate system (Figure 7.2). Virtually all the energy that enters or leaves the climate system does so in the form of radiation at the TOA. The TOA energy budget is determined by the amount of incoming solar (shortwave) radiation and the outgoing radiation that is composed of reflected solar radiation and outgoing thermal (longwave) radiation emitted by the climate system. In a steady state climate, the outgoing and incoming radiative components are essentially in balance in the long-term global mean, although there are still fluctuations around this balanced state that arise through internal climate variability (Brown et al., 2014; Palmer and McNeall, 2014). However, anthropogenic forcing has given rise to a persistent imbalance in the global mean TOA radiation budget that is often referred to as Earth's energy imbalance (e.g., Trenberth et al., 2014; von Schuckmann et al., 2016) and is a key element in energy budget framework (N, Box 7.1, Equation 7.1) and an important metric of the rate of global climate change (Hansen et al., 2005a; von Schuckmann et al., 2020). In addition to the TOA energy fluxes, Earth's energy budget also includes the internal flows of energy within the climate

ACCEPTED VERSION SUBJECT TO FINAL EDITING

system, which characterize the climate state. The surface energy budget consists of the net solar and thermal radiation as well as the non-radiative components such as sensible, latent and ground heat fluxes (Figure 7.2 upper panel). It is a key driver of the global water cycle, atmosphere and ocean dynamics, as well as a variety of surface processes.

7.2.1 Present-day energy budget

Figure 7.2 (upper panel) shows a schematic representation of Earth's energy budget for the early 21st century, including globally-averaged estimates of the individual components (Wild et al., 2015). Clouds are important modulators of the global energy fluxes. Thus, any perturbations in the cloud fields, such as forced by aerosol-cloud interactions (Section 7.3) or through cloud feedbacks (Section 7.4) can have a strong influence on the energy distribution in the climate system. To illustrate the overall effects that clouds exert on the energy fluxes, Figure 7.2 (lower panel) also shows the energy budget in the absence of clouds, with otherwise identical atmospheric and surface radiative properties. It has been derived by taking into account information contained in both in-situ and satellite radiation measurements taken under cloud-free conditions (Wild et al., 2019). A comparison of the upper and lower panels in Figure 7.2 shows that without clouds, 47 W m^{-2} less solar radiation is reflected back to space globally (53 ± 2 W m^{-2} instead of 100 ± 2 W m^{-2}), while 28 W m^{-2} more thermal radiation is emitted to space (267 ± 3 W m^{-2} instead of 239± 3 W m^{-2}). As a result, there is a 20 W m^{-2} radiative imbalance at the TOA in the clear-sky energy budget (Figure 7.2 lower panel), suggesting that the Earth would warm substantially if there were no clouds.

[START FIGURE 7.2 HERE]

Figure 7.2: Schematic representation of the global mean energy budget of the Earth (upper panel), and its equivalent without considerations of cloud effects (lower panel). Numbers indicate best estimates for the magnitudes of the globally averaged energy balance components in W m^{-2} together with their uncertainty ranges in parentheses (5–95 % confidence range), representing climate conditions at the beginning of the 21st century. Note that the cloud-free energy budget shown in the lower panel is not the one that Earth would achieve in equilibrium when no clouds could form. It rather represents the global mean fluxes as determined solely by removing the clouds but otherwise retaining the entire atmospheric structure. This enables the quantification of the effects of clouds on the Earth energy budget and corresponds to the way clear-sky fluxes are calculated in climate models. Thus, the cloud-free energy budget is not closed and therefore the sensible and latent heat fluxes are not quantified in the lower panel. Adapted from Wild et al. (2015, 2019).

[END FIGURE 7.2 HERE]

AR5 (Church et al., 2013; Hartmann et al., 2013; Myhre et al., 2013b) highlighted the progress in quantifying the TOA radiation budget following new satellite observations that became available in the early 21st Century (Clouds and the Earth's Radiant Energy System, CERES; Solar Radiation and Climate Experiment, SORCE). Progress in the quantification of changes in incoming solar radiation at the TOA is discussed in Chapter 2, Section 2.2. Since AR5, the CERES Energy Balance EBAF Ed4.0 product was released, which includes algorithm improvements and consistent input datasets throughout the record (Loeb et al., 2018a). However, the overall precision of these fluxes (uncertainty in global mean TOA flux 1.7% (1.7 W m^{-2}) for reflected solar and 1.3% (3.0 W m^{-2}) for outgoing thermal radiation at the 90% confidence level) is not sufficient to quantify the Earth's energy imbalance in absolute terms. Therefore, adjustments within the uncertainty ranges of the CERES reflected solar and emitted thermal TOA fluxes were applied to the entire EBAF record to ensure that the net TOA flux for July 2005–June 2015 was consistent with the estimated Earth's energy imbalance for the same period based on ocean heat content (OHC) measurements and energy uptake estimates for the land, cryosphere and atmosphere (Johnson et al., 2016; Riser et al., 2016; Section 7.2.2.2). ESMs typically show good agreement with global mean TOA fluxes from CERES-EBAF. However, as some ESMs are known to calibrate their TOA fluxes to CERES or similar data (Hourdin et al., 2017), this is not necessarily an indication of model accuracy, especially as ESMs show significant

ACCEPTED VERSION SUBJECT TO FINAL EDITING

discrepancies on regional scales, often related to their representation of clouds (Trenberth and Fasullo, 2010; Donohoe and Battisti, 2012; Hwang and Frierson, 2013; Li et al., 2013b; Dolinar et al., 2015; Wild et al., 2015).

The radiation components of the surface energy budget are associated with substantially larger uncertainties than at the TOA, since they are less directly measured by passive satellite sensors from space and require retrieval algorithms and ancillary data for their estimation (Raschke et al., 2016; Kato et al., 2018; Huang et al., 2019). Confidence in the quantification of the global mean surface radiation components has increased recently, as independent estimates now converge to within a few W m^{-2} (Wild, 2017). Current best estimates for downward solar and thermal radiation at Earth's surface are near 185 W m^{-2} and 342 W m^{-2}, respectively (Figure 7.2). These estimates are based on complementary approaches that make use of satellite products from active and passive sensors (L'Ecuyer et al., 2015; Kato et al., 2018) and information from surface observations and Earth System Models (ESMs) (Wild et al., 2015). Inconsistencies in the quantification of the global mean energy and water budgets discussed in AR5 (Hartmann et al., 2013) have been reconciled within the (considerable) uncertainty ranges of their individual components (Wild et al., 2013, 2015; L'Ecuyer et al., 2015). However, on regional scales, the closure of the surface energy budgets remains a challenge with satellite-derived datasets (Loeb et al., 2014; L'Ecuyer et al., 2015; Kato et al., 2016). Nevertheless, attempts have been made to derive surface energy budgets over land and ocean (Wild et al., 2015), over the Arctic (Christensen et al., 2016a) and over individual continents and ocean basins (L'Ecuyer et al., 2015; Thomas et al., 2020). Since AR5, the quantification of the uncertainties in surface energy flux datasets has improved. Uncertainties in global monthly mean downward solar and thermal fluxes in the CERES-EBAF surface dataset are, respectively, 10 W m^{-2} and 8 W m^{-2} (converted to 5% to 95% ranges) (Kato et al., 2018). The uncertainty in the surface fluxes for polar regions is larger than in other regions (Kato et al., 2018) due to the limited number of surface sites and larger uncertainty in surface observations (Previdi et al., 2015). The uncertainties in ocean mean latent and sensible heat fluxes are approximately 11 W m^{-2} and 5 W m^{-2} (converted to 5% to 95% ranges), respectively (L'Ecuyer et al., 2015). A recent review of the latent and sensible heat flux accuracies over the period 2000 to 2007 highlights significant differences between several gridded products over ocean, where root mean squared differences between the multi-product ensemble and data at more than 200 moorings reached up to 25 W m^{-2} for latent heat and 5 W m^{-2} for sensible heat (Bentamy et al., 2017). This uncertainty stems from the retrieval of flux-relevant meteorological variables, as well as from differences in the flux parameterizations (Yu, 2019). Estimating the uncertainty in sensible and latent heat fluxes over land is difficult because of the large temporal and spatial variability. The flux values over land computed with three global datasets vary by 10% to 20% (L'Ecuyer et al., 2015).

ESMs also show larger discrepancies in their surface energy fluxes than at the TOA due to weaker observational constraints, with a spread of typically 10-20 W m^{-2} in the global average, and an even greater spread at regional scales (Li et al., 2013b; Wild et al., 2013; Boeke and Taylor, 2016; Wild, 2017; Zhang et al., 2018a; Wild, 2020). Differences in the land-averaged downward thermal and solar radiation in CMIP5 ESMs amount to more than 30 and 40 W m^{-2}, respectively (Wild et al., 2015). However, in the global multi-model mean, the magnitudes of the energy budget components of the CMIP6 ESMs generally show better agreement with reference estimates than previous model generations (Wild, 2020).

In summary, since AR5, the magnitudes of the global mean energy budget components have been quantified more accurately, not only at the TOA, but also at the Earth's surface, where independent estimates of the radiative components have converged (*high confidence*). Considerable uncertainties remain in regional surface energy budget estimates as well as their representation in climate models.

7.2.2 Changes in Earth's energy budget

7.2.2.1 Changes in Earth's TOA energy budget

Since 2000, changes in the TOA energy fluxes can be tracked from space using CERES satellite observations (Figure 7.3). The variations in TOA energy fluxes reflect the influence of internal climate

ACCEPTED VERSION SUBJECT TO FINAL EDITING

variability, particularly that of ENSO, in addition to radiative forcing of the climate system and climate feedbacks (Allan et al., 2014; Loeb et al., 2018a). For example, globally, the reduction in both outgoing thermal and reflected solar radiation during La Niña conditions in 2008/2009 led to an energy gain for the climate system, whereas enhanced outgoing thermal and reflected solar radiation caused an energy loss during the El Niños of 2002/2003 and 2009/2010 (Figure 7.3; Loeb et al., 2018a). An ensemble of CMIP6 models is able to track the variability in the global mean TOA fluxes observed by CERES, when driven with prescribed sea-surface temperatures (SSTs) and sea-ice concentrations (Figure 7.3; Loeb et al., 2020). Under cloud-free conditions, the CERES record shows a near zero trend in outgoing thermal radiation (Loeb et al., 2018a), which combined with an increasing surface upwelling thermal flux implies an increasing clear-sky greenhouse effect (Raghuraman et al., 2019). Conversely, clear-sky solar reflected TOA radiation in the CERES record covering March 2000 to September 2017 shows a decrease due to reductions in aerosol optical depth in the Northern Hemisphere and sea-ice fraction (Loeb et al., 2018b; Paulot et al., 2018).

An effort to reconstruct variations in the net TOA fluxes back to 1985, based on a combination of satellite data, atmospheric reanalysis and high-resolution climate model simulations (Allan et al., 2014; Liu et al., 2020), exhibits strong interannual variability associated with the volcanic eruption of Mt Pinatubo in 1991 and the ENSO events before 2000. The same reconstruction suggests that Earth's energy imbalance increased by several tenths of a W m^{-2} between the periods 1985–1999 and 2000–2016, in agreement with the assessment of changes in the global energy inventory (Section 7.2.2.2, Box 7.2, Figure 1). Comparisons of year-to-year variations in Earth's energy imbalance estimated from CERES and independent estimates based on ocean heat content change are significantly correlated with similar phase and magnitude (Johnson et al., 2016; Meyssignac et al., 2019), promoting confidence in both satellite and in situ-based estimates (Section 7.2.2.2).

In summary, variations in the energy exchange between Earth and space can be accurately tracked since the advent of improved observations since the year 2000 (*high confidence*), while reconstructions indicate that the Earth's energy imbalance was larger in the 2000s than in the 1985–1999 period (*high confidence*).

[START FIGURE 7.3 HERE]

Figure 7.3: Anomalies in global mean all-sky TOA fluxes from EBAF Ed4.0 (solid black lines) and various CMIP6 climate models (coloured lines) in terms of (a) reflected solar, (b) emitted thermal and (c) net TOA fluxes. The multi-model means are additionally depicted as dotted black lines. Model fluxes stem from simulations driven with prescribed SSTs and all known anthropogenic and natural forcings. Shown are anomalies of 12-month running means. All flux anomalies are defined as positive downwards, consistent with the sign convention used throughout this chapter. The correlations between the multi-model means (dotted black lines) and the CERES records (solid black lines) for 12-month running means are 0.85, 0.73 and 0.81 for the global mean reflected solar, outgoing thermal and net TOA radiation, respectively. Adapted from Loeb et al. (2020). Further details on data sources and processing are available in the chapter data table (Table 7.SM.14).

[END FIGURE 7.3 HERE]

7.2.2.2 Changes in the global energy inventory

The global energy inventory quantifies the integrated energy gain of the climate system associated with global ocean heat uptake, warming of the atmosphere, warming of the land, and melting of ice. Due to energy conservation, the rate of accumulation of energy in the Earth system (Section 7.1) is equivalent to the Earth energy imbalance (N in Box 7.1, Equation 7.1). On annual and longer timescales, changes in the global energy inventory are dominated by changes in global OHC (Rhein et al., 2013; Palmer and McNeall, 2014; Johnson et al., 2016). Thus, observational estimates and climate model simulations of OHC change are critical to the understanding of both past and future climate change (Chapter 2, Section 2.3.3.1, Chapter 3, Section 3.5.1.3, Chapter 4, Section 4.5.2.1, Chapter 9, Section 9.2.2.1).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Since AR5, both modelling and observational-based studies have established Earth's energy imbalance (characterised by OHC change) as a more robust metric of the rate of global climate change than GSAT on interannual-to-decadal timescales (Palmer and McNeall, 2014; von Schuckmann et al., 2016; Wijffels et al., 2016; Cheng et al., 2018; Allison et al., 2020a). This is because GSAT is influenced by large unforced variations, for example linked to ENSO and Pacific decadal variability (Roberts et al., 2015; Yan et al., 2016; Cheng et al., 2018). Measuring OHC change more comprehensively over the full ocean depth results in a higher signal-to-noise ratio and a timeseries that increases steadily over time (Box7.2, Figure 1; Allison et al., 2020). In addition, understanding of the potential effects of historical ocean sampling on estimated global ocean heating rates has improved (Durack et al., 2014; Good, 2017; Allison et al., 2019) and there are now more estimates of OHC change available that aim to mitigate the effect of limited observational sampling in the Southern Hemisphere (Lyman and Johnson, 2008; Cheng et al., 2017; Ishii et al., 2017).

The assessment of changes in the global energy inventory for the periods 1971-2018, 1993-2018 and 2006–2018 draws upon the latest observational timeseries and the assessments presented in other chapters of this report. The estimates of OHC change come directly from the assessment presented in Chapter 2, Section 2.3.3.1. The assessment of land and atmospheric heating comes from von Schuckmann et al. (2020), based on the estimates of Cuesta-Valero et al. (2021) and Steiner et al. (2020), respectively. Heating of inland waters, including lakes, reservoirs and rivers, is estimated to account for < 0.1 % of the total energy change, and is therefore neglected from this assessment (Vanderkelen et al., 2020). The cryosphere contribution from melting of grounded ice is based on the mass loss assessments presented in Chapter 9, Sections 9.4.1 (Greenland ice sheet), 9.4.2 (Antarctic ice sheet) and 9.5.1 (glaciers). Following AR5, the estimate of heating associated with loss of Arctic sea ice is based on a reanalysis (Schweiger et al., 2011), following the methods described by Slater et al. (2021). Chapter 9, Section 9.3.2 finds no significant trend in Antarctic sea ice area over the observational record, a zero contribution is assumed. Ice melt associated with the calving and thinning of floating ice shelves are based on the decadal rates presented in Slater et al. (2021). For all cryospheric components, mass loss is converted to heat input using a latent heat of fusion of 3.34×10^5 J Kg^{-1} C^{-1} with the second-order contributions from variations associated with ice type and warming of ice from sub-freezing temperatures neglected, as in AR5. The net change in energy, quantified in Zetta Joules (1 ZJ = 10^{21} Joules), is computed for each component as the difference between the first and last year of each period (Table 7.1). The uncertainties in the depth-interval contributions to OHC are summed to get the uncertainty in global OHC change. All other uncertainties are assumed to be independent and added in quadrature.

[START TABLE 7.1 HERE]

Table 7.1: Contributions of the different components of the global energy inventory for the periods 1971 to 2018, 1993 to 2018 and 2006 to 2018 (Box 7.2, Cross-chapter box 9.1). Energy changes are computed as the difference between annual mean values or year mid-points. The total heating rates correspond to Earth's energy imbalance and are expressed per unit area of Earth's surface.

Component	1971 to 2018		1993 to 2018		2006 to 2018	
	Energy Gain (ZJ)	%	Energy Gain (ZJ)	%	Energy Gain (ZJ)	%
Ocean	396.0 [285.7 to 506.2]	91.0	263.0 [194.1 to 331.9]	90.9	138.8 [86.4 to 191.3]	90.7
0-700 m	241.6 [162.7 to 320.5]	55.6	151.5 [114.1 to 188.9]	52.4	75.4 [48.7 to 102.0]	49.3
700-2000 m	123.3 [96.0 to 150.5]	28.3	82.8 [59.9 to 105.6]	28.6	49.7 [29.0 to 70.4]	32.4
> 2000 m	31.0 [15.7 to 46.4]	7.1	28.7 [14.5 to 43.0]	9.9	13.8 [7.0 to 20.6]	9.0
Land	21.8 [18.6 to 25.0]	5.0	13.7 [12.4 to 14.9]	4.7	7.2 [6.6 to 7.8]	4.7
Cryosphere	11.5 [9.0 to 14.0]	2.7	8.8 [7.0 to 10.6]	3.0	5.4 [3.9 to 6.8]	3.5
Atmosphere	5.6 [4.6 to 6.7]	1.3	3.8 [3.2 to 4.3]	1.3	1.6 [1.2 to 2.1]	1.1
TOTAL	**434.9 [324.5 to 545.5] ZJ**		**289.2 [220.3 to 358.2] ZJ**		**153.1 [100.6 to 205.5] ZJ**	

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Heating Rate	**0.57 [0.43 to 0.72] W m^{-2}**	**0.72 [0.55 to 0.89] W m^{-2}**	**0.79 [0.52 to 1.06] W m^{-2}**

[END TABLE 7.1 HERE]

For the period 1971–2010, AR5 (Rhein et al., 2013) found an increase in the global energy inventory of 274 [196 to 351] ZJ with a 93% contribution from total OHC change, about 3% for both ice melt and land heating, and about 1% for warming of the atmosphere. For the same period, this Report finds an upwards revision of OHC change for the upper (< 700 m depth) and deep (> 700 m depth) ocean of about 8% and 20% compared to AR5 and a modest increase in the estimated uncertainties associated with the ensemble approach of Palmer et al. (2021). The other substantive change compared to AR5 is the updated assessment of land heating, with values approximately double those assessed previously, based on a more comprehensive analysis of the available observations (von Schuckmann et al., 2020; Cuesta-Valero et al., 2021). The result of these changes is an assessed energy gain of 329 [224 to 434] ZJ for the period 1971–2010, which is consistent with AR5 within the estimated uncertainties, despite the systematic increase.

The assessed changes in the global energy inventory (Box 7.2, Figure 1a; Table 7.1) yields an average value for Earth's energy imbalance (*N*, Box 7.1, Equation 7.1) of 0.57 [0.43 to 0.72] W m^{-2} for the period 1971 to 2018, expressed relative to Earth's surface area (*high confidence*). The estimates for the periods 1993 to 2018 and 2006 to 2018 yield substantially larger values of 0.72 [0.55 to 0.89] W m^{-2} and 0.79 ± [0.52 to 1.06] W m^{-2}, respectively, consistent with the increased radiative forcing from greenhouse gases (*high confidence*). To put these numbers in context, the 2006–2018 average Earth system heating is equivalent to approximately 20 times the rate of global energy consumption in 2018[1].

Consistent with AR5 (Rhein et al., 2013), ocean warming dominates the changes in total Earth system heating (*high confidence*), accounting for 91% of the observed change for all periods considered (Table 7.1). The contributions from the other components across all periods are approximately 5% from land heating, 3% for cryosphere heating and 1% associated with warming of the atmosphere (*high confidence*). The assessed percentage contributions are similar to the recent study by von Schuckmann et al. (2020) and the total heating rates are consistent within the assessed uncertainties. Cross-validation of heating rates based on satellite and in situ observations (Section 7.2.2.1) and closure of the global sea-level budget using consistent datasets (Cross-Chapter Box 9.1; Chapter 9, Table 9.5) strengthen scientific confidence in the assessed changes in the global energy inventory relative to AR5.

7.2.2.3 Changes in Earth's surface energy budget

AR5 (Hartmann et al., 2013) reported pronounced changes in multi-decadal records of in situ observations of surface solar radiation, including a widespread decline between the 1950s and 1980s, known as "global dimming", and a partial recovery thereafter, termed "brightening" (see also Chapter 12, Section 12.4). Over the past decades, these changes have interacted with closely-related elements of climate change, such as global and regional warming rates (Li et al., 2016b; Wild, 2016; Du et al., 2017; Zhou et al., 2018a), glacier melt (Ohmura et al., 2007; Huss et al., 2009), the intensity of the global water cycle (Wild, 2012) and terrestrial carbon uptake (Mercado et al., 2009). These observed changes have also been used as emergent constraints to quantify aerosol effective radiative forcing (see Section 7.3.3.3).

Since AR5, additional evidence for dimming and/or subsequent brightening up to several percent per decade, based on direct surface observations, has been documented in previously less studied areas of the globe, such as in Iran, Bahrain, Tenerife, Hawaii, the Taklaman desert and the Tibetan Plateau (Elagib and Alvi, 2013; You et al., 2013; Garcia et al., 2014; Longman et al., 2014; Rahimzadeh et al., 2015). Strong decadal trends in surface solar radiation remain evident after careful data quality assessment and homogenization of long-

[1] https://ourworldindata.org/energy, accessed 13 April 2021

ACCEPTED VERSION SUBJECT TO FINAL EDITING

term records (Sanchez-Lorenzo et al., 2013; Manara et al., 2015; Sanchez-Lorenzo et al., 2015; Wang et al., 2015; Li et al., 2016b; Manara et al., 2016; Wang and Wild, 2016; He et al., 2018b; Yang et al., 2018). Since AR5, new studies on the potential effects of urbanization on solar radiation trends indicate that these effects are generally small, with the exception of some specific sites in Russia and China (Wang et al., 2014; Imamovic et al., 2016; Tanaka et al., 2016). Also, surface-based solar radiation observations have been shown to be representative over large spatial domains of up to several degrees latitude/longitude on monthly and longer timescales (Hakuba et al., 2014; Schwarz et al., 2018). Thus, there is *high confidence* that the observed dimming between the 1950s and 1980s and subsequent brightening are robust and do not arise from measurement artefacts or localised phenomena.

As noted in AR5 (Hartmann et al., 2013) and supported by recent studies, the trends in surface solar radiation are less spatially coherent since the beginning of the 21st century, with evidence for continued brightening in parts of Europe and the USA, some stabilization in China and India, and dimming in other areas (Augustine and Dutton, 2013; Sanchez-Lorenzo et al., 2015; Manara et al., 2016; Soni et al., 2016; Wang and Wild, 2016; Jahani et al., 2018; Pfeifroth et al., 2018; Yang et al., 2018; Schwarz et al., 2020). The CERES-EBAF satellite-derived dataset of surface solar radiation (Kato et al., 2018) does not indicate a globally significant trend over the short period 2001–2012 (Zhang et al., 2015), whereas a statistically significant increase in surface solar radiation of +3.4 W m^{-2} per decade over the period 1996–2010 has been found in the Satellite Application Facility on Climate Monitoring (CM SAF) record of the geostationary satellite Meteosat, which views Europe, Africa and adjacent ocean (Posselt et al., 2014).

Since AR5 there is additional evidence that strong decadal changes in surface solar radiation have occurred also under cloud-free conditions, as shown for long term observational records in Europe, USA, China, India and Japan (Xu et al., 2011; Gan et al., 2014; Manara et al., 2016; Soni et al., 2016; Tanaka et al., 2016; Kazadzis et al., 2018; Li et al., 2018a; Yang et al., 2019; Wild et al., 2021). This suggests that changes in the composition of the cloud-free atmosphere, primarily in aerosols, contributed to these variations, particularly since the second half of the 20th century (Wild, 2016). Water vapour and other radiatively active gases seem to have played a minor role (Wild, 2009; Mateos et al., 2013; Posselt et al., 2014; Yang et al., 2019). For Europe and East Asia, modelling studies also point to aerosols as an important factor for dimming and brightening by comparing simulations that include/exclude variations in anthropogenic aerosol and aerosol-precursor emissions (Golaz et al., 2013; Nabat et al., 2014; Persad et al., 2014; Folini and Wild, 2015; Turnock et al., 2015; Moseid et al., 2020). Moreover, decadal changes in surface solar radiation have often occurred in line with changes in anthropogenic aerosol emissions and associated aerosol optical depth (Streets et al., 2006; Wang and Yang, 2014; Storelvmo et al., 2016; Wild, 2016; Kinne, 2019). However, further evidence for the influence of changes in cloudiness on dimming and brightening is emphasized in some studies (Augustine and Dutton, 2013; Parding et al., 2014; Stanhill et al., 2014; Pfeifroth et al., 2018; Antuña-Marrero et al., 2019). Thus, the contribution of aerosol and clouds to dimming and brightening is still debated. The relative influence of cloud-mediated aerosol effects versus direct aerosol radiative effects on dimming and brightening in a specific region may depend on the prevailing pollution levels (Wild, 2016; Section 7.3.3).

ESMs and reanalyses often do not reproduce the full extent of observed dimming and brightening (Wild and Schmucki, 2011; Allen et al., 2013; Zhou et al., 2017a; Storelvmo et al., 2018; Moseid et al., 2020; Wohland et al., 2020), potentially pointing to inadequacies in the representation of aerosol mediated effects or related emission data. The inclusion of assimilated aerosol optical depth inferred from satellite retrievals in the MERRA2 reanalysis (Buchard et al., 2017; Randles et al., 2017) helps to improve the accuracy of the simulated surface solar radiation changes in China (Feng and Wang, 2019). However, non-aerosol related deficiencies in model representations of clouds and circulation, and/or an underestimation of natural variability, could further contribute to the lack of dimming and brightening in ESMs (Wild, 2016; Storelvmo et al., 2018).

AR5 reported evidence for an increase in surface downward thermal radiation based on different studies covering in total 1964–2008, in line with expectation from an increased radiative forcing from greenhouse gases and the warming and moistening of the atmosphere. Updates of the longest observational records from the Baseline Surface Radiation Network continue to show an increase at the majority of the sites, in line with

ACCEPTED VERSION SUBJECT TO FINAL EDITING

an overall increase predicted by ESMs on the order of 2 W m^{-2} $decade^{-1}$ (Wild, 2016). Upward longwave radiation at the surface is rarely measured but expected to have increased over the same period due to rising surface temperatures.

Turbulent fluxes of latent and sensible heat are also an important part of the surface energy budget (Figure 7.2). Large uncertainties in measurements of surface turbulent fluxes continue to prevent the determination of their decadal changes. Nevertheless, over the ocean, reanalysis-based estimates of linear trends from 1948 to 2008 indicate high spatial variability and seasonality. Increases in magnitudes of 4 to 7 W m^{-2} $decade^{-1}$ for latent heat and 2 to 3 W m^{-2} $decade^{-1}$ for sensible heat in the western boundary current regions are mostly balanced by decreasing trends in other regions (Gulev and Belyaev, 2012). Over land, the terrestrial latent heat flux is estimated to have increased in magnitude by 0.09 W m^{-2} $decade^{-1}$ from 1989 to 1997, and subsequently decreased by 0.13 W m^{-2} $decade^{-1}$ from 1998 to 2005 due to soil moisture limitation mainly in the Southern Hemisphere (derived from Mueller et al. (2013)). These trends are small in comparison to the uncertainty associated with satellite-derived and in-situ observations, as well as from land surface models forced by observations and atmospheric reanalyses. Ongoing advances in remote sensing of evapotranspiration from space (Mallick et al., 2016; Fisher et al., 2017; McCabe et al., 2017b, 2017a), as well as terrestrial water storage (Rodell et al., 2018) may contribute to future constraints on changes in latent heat flux.

In summary, since AR5, multidecadal trends in surface solar radiation up to several percent per decade have been detected at many more locations also in remote areas. There is *high confidence* that these trends are widespread, and not localised phenomena or measurement artefacts. The origin of these trends is not fully understood, although there is evidence that anthropogenic aerosols have made a substantial contribution (*medium confidence*). There is *medium confidence* that downward and upward thermal radiation has increased since the 1970s, while there remains *low confidence* in the trends in surface sensible and latent heat.

[START BOX 7.2 HERE]

BOX 7.2: The Global Energy Budget

This box assesses the present knowledge of the global energy budget for the period 1971–2018, i.e. the balance between radiative forcing, the total climate feedback and observations of the changes in the global energy inventory (Box 7.2, Figure 1a, d).

The net ERF of the Earth system since 1971 has been positive (Box 7.2, Figure 1b, e; Section 7.3), mainly as a result of increases in atmospheric greenhouse gas concentrations (Chapter 2, Section 2.2.8 and Section 7.3.2). The ERF of these positive forcing agents have been partly offset by that of negative forcing agents, primarily due to anthropogenic aerosols (Section 7.3.3), which dominate the overall uncertainty. The net energy inflow to the Earth system from ERF since 1971 is estimated to be 937 ZJ (1 ZJ = 10^{21} J) with a *likely* range of 644 to 1259 ZJ (Box 7.2, Figure 1b).

The ERF-induced heating of the climate system results in increased thermal radiation to space via the Planck response, but the picture is complicated by a variety of climate feedbacks (Box 7.1; Section 7.4.2) that also influence Earth's radiative response (Box 7.2, Figure 1c). The total radiative response is estimated by multiplying the assessed net feedback parameter, α, from process-based evidence (Section 7.4.2, Table 7.10) with the observed GSAT change for the period (Chapter 2, Cross Chapter Box 2.3) and time-integrating (Box 7.2, Figure 1c). The net energy outflow from the Earth system associated with the integrated radiative response 1971 is estimated to be 621 ZJ with a *likely* range of 419 to 823 ZJ. Assuming a pattern effect (Section 7.4.4) on α of -0.5 W m^{-2} C^{-1} would lead to a systematically larger energy outflow by about 250 ZJ.

Combining the *likely* range of integrated radiative forcing (Box 7.2, Figure 1b) with the central estimate of integrated radiative response (Box 7.2, Figure 1c) gives a central estimate and *likely* range of 340 [47 to 662] ZJ (Box 7.2, Figure 1f). Combining the *likely* range of integrated radiative response with the central estimate

ACCEPTED VERSION SUBJECT TO FINAL EDITING

of integrated radiative forcing gives a *likely* range of 340 [147 to 527] ZJ (Box 7.2, Figure 1f). Both calculations yield an implied energy gain in the climate system that is consistent with an independent observation-based assessment of the increase in the global energy inventory expressed relative to the estimated 1850-1900 Earth energy imbalance (Box 7.2, Figure 1a; Section 7.5.2) with a central estimate and *very likely* range of 284 [96 to 471] ZJ (*high confidence*) (Box 7.2, Figure 1d; Table 7.1). Estimating the total uncertainty associated with radiative forcing and radiative response remains a scientific challenge and depends on the degree of correlation among the two (Box 7.2, Figure 1f). However, the central estimate of observed energy change falls well with the estimated *likely* range assuming either correlated or uncorrelated uncertainties. Furthermore, the energy budget assessment would accommodate a substantial pattern effect (Section 7.4.4.3) during 1971–2018 associated with systematically larger values of radiative response (Box 7.2, Figure 1c), and potentially improved closure of the global energy budget. For the period 1970-2011, AR5 reported that the global energy budget was closed within uncertainties (*high confidence*) and consistent with the *likely* range of assessed climate sensitivity (Church et al., 2013). This report provides a more robust quantitative assessment based on additional evidence and improved scientific understanding.

In addition to new and extended observations (Section 7.2.2), confidence in the observed accumulation of energy in the Earth system is strengthened by cross-validation of heating rates based on satellite and in situ observations (Section 7.2.2.1) and closure of the global sea-level budget using consistent datasets (Cross-Chapter Box 9.1; Chapter 9, Table 9.5). Overall, there is *high confidence* that the global energy budget is closed for 1971–2018 with improved consistency compared to AR5

[START BOX 7.2, FIGURE 1 HERE]

Box 7.2, Figure 1: Estimates of the net cumulative energy change (ZJ = 10^{21} Joules) for the period 1971–2018 associated with: (a) observations of changes in the Global Energy Inventory (b) Integrated Radiative Forcing; (c) Integrated Radiative Response. Black dotted lines indicate the central estimate with *likely* and *very likely* ranges as indicated in the legend. The grey dotted lines indicate the energy change associated with an estimated pre-industrial Earth energy imbalance of 0.2 W m^{-2} (panel a) and an illustration of an assumed pattern effect of –0.5 W m^{-2} °C^{-1} (panel c). Background grey lines indicate equivalent heating rates in W m^{-2} per unit area of Earth's surface. Panels (d) and (e) show the breakdown of components, as indicated in the legend, for the Global Energy Inventory and Integrated Radiative Forcing, respectively. Panel (f) shows the Global Energy Budget assessed for the period 1971–2018, i.e. the consistency between the change in the Global Energy Inventory relative to pre-industrial and the implied energy change from Integrated Radiative Forcing plus Integrated Radiative Response under a number of different assumptions, as indicated in the figure legend, including assumptions of correlated and uncorrelated uncertainties in Forcing plus Response. Shading represents the *very likely* range for observed energy change relative to pre-industrial and *likely* range for all other quantities. Forcing and Response timeseries are expressed relative to a baseline period of 1850–1900. Further details on data sources and processing are available in the chapter data table (Table 7.SM.14).

[END BOX 7.2 HERE]

7.3 Effective radiative forcing

Effective radiative forcing (ERF) quantifies the energy gained or lost by the Earth system following an imposed perturbation (for instance in greenhouse gases, aerosols or solar irradiance). As such it is a fundamental driver of changes in the Earth's TOA energy budget. ERF is determined by the change in the net downward radiative flux at the TOA (see Box 7.1) after the system has adjusted to the perturbation but excluding the radiative response to changes in surface temperature. This section outlines the methodology for ERF calculations in Section 7.3.1 and then assesses the ERF due to greenhouse gases in Section 7.3.2, aerosols in Section 7.3.3 and other natural and anthropogenic forcing agents in Section 7.3.4. These are brought together in Section 7.3.5 for an overall assessment of the present-day ERF and its evolution over the

ACCEPTED VERSION SUBJECT TO FINAL EDITING

historical time period since 1750 until 2019. The same section also evaluates the surface temperature response to individual ERFs.

7.3.1 Methodologies and representation in models; overview of adjustments

As introduced in Box 7.1, AR5 (Boucher et al., 2013; Myhre et al., 2013b) recommended ERF as a more useful measure of the climate effects of a physical driver than the stratospheric-temperature-adjusted radiative forcing (SARF) adopted in earlier assessments. AR5 assessed that the ratios of surface temperature change to forcing resulting from perturbations of different forcing agents were more similar between species using ERF than SARF. ERF extended the SARF concept to account for not only adjustments to stratospheric temperatures, but also responses in the troposphere and effects on clouds and atmospheric circulation, referred to as "adjustments". For more details see Box 7.1. Since circulation can be affected, these responses are not confined to the locality of the initial perturbation (unlike the traditional stratospheric-temperature adjustment).

This chapter defines "adjustments" as those changes caused by the forcing agent that are independent of changes in surface temperature, rather than defining a specific timescale. AR5 used the terminology "rapid adjustment", but in this assessment the definition is based on the independence from surface temperature rather than the rapidity. The definition of ERF in Box 7.1 aims to have a clean separation between forcing (energy budget changes that are not mediated by surface temperature) and feedbacks (energy budget changes that are mediated by surface temperature). This means that changes in land or ocean surface temperature patterns (for instance as identified by Rugenstein et al. (2016b)) are not included as adjustments. As in previous assessments (Forster et al., 2007; Myhre et al., 2013b) ERFs can be attributed simply to changes in the forcing agent itself or attributed to components of emitted gases (see Chapter 6, Figure 6.12). Because ERFs can include chemical and biospheric responses to emitted gases, they can be attributed to precursor gases even if those gases do not have a direct radiative effect themselves. Similar chemical and biospheric responses to forcing agents can also be included in the ERF in addition to their direct effects.

Instantaneous Radiative Forcing (IRF) is defined here as the change in the net TOA radiative flux following a perturbation, excluding any adjustments. SARF is defined here as the change in the net radiative flux at TOA following a perturbation including the response to stratospheric temperature adjustments. These differ from AR5 where these quantities were defined at the tropopause (Myhre et al., 2013b). The net IRF values will be different using the TOA definition. The net SARF values will be the same as with the tropopause definition, but will have a different partitioning between the longwave and shortwave. Defining all quantities at the TOA enables consistency in breaking down the ERF into its component parts.

The assessment of ERFs in AR5 was preliminary because ERFs were only available for a few forcing agents, so for many forcing agents the report made the assumption that ERF and SARF were equivalent. A body of work published since AR5 is discussed in this section that has computed ERFs across many more forcing agents and models, closely examined the methods of computation, quantified the processes involved in causing adjustments and examined how well ERFs predict the ultimate temperature response. This work is assessed to have led to a much-improved understanding and increased confidence in the quantification of radiative forcing across the Report. These same techniques allow for an evaluation of radiative forcing within Earth System Models (ESMs) as a key test of their ability to represent both historical and future temperature changes (Chapter 3, Section 3.3.1 and Chapter 4, Section 4.3.4).

The ERF for a particular forcing agent is the sum of the IRF and the contribution from the adjustments, so in principle this could be constructed bottom-up by calculating the IRF and adding in the adjustment contributions one-by-one or together. However, there is no simple way to derive the global tropospheric adjustment terms or adjustments related to circulation changes without using a comprehensive climate model (e.g., CMIP5/6). There have been two main modelling approaches used to approximate the ERF definition in Box 7.1. The first approach is to use the assumed linearity (Equation 7.1) to regress the net change in the TOA radiation budget (ΔN) against change in global mean surface temperature (ΔT) following a step change in the forcing agent (Gregory et al., 2004; Box 7.1, Figure 1). The ERF (ΔF) is then derived from ΔN when

ACCEPTED VERSION SUBJECT TO FINAL EDITING

ΔT=0. Regression-based estimates of ERF depend on the temporal resolution of the data used (Modak et al., 2016, 2018). For the first few months of a simulation both surface temperature change and stratospheric temperature adjustment occur at the same time, leading to misattribution of the stratospheric temperature adjustment to the surface temperature feedback. Patterns of sea-surface temperature change also affect estimates of the forcing obtained by regression methods (Andrews et al., 2015). At multidecadal timescales the curvature of the relationship between net TOA radiation and surface temperature can also lead to biases in the ERF estimated from the regression method (Armour et al., 2013; Andrews et al., 2015; Knutti et al., 2017; Section 7.4). The second modelling approach to estimate ERF is to set the ΔT term in Box 7.1 (Equation 7.1) to zero. It is technically difficult to constrain land surface temperatures in ESMs (Shine et al., 2003; Ackerley and Dommenget, 2016; Andrews et al., 2021), so most studies reduce the ΔT term by prescribing the SSTs and sea-ice concentrations in a pair of "fixed-SST" (fSST) simulations with and without the change in forcing agent (Hansen et al., 2005b). An approximation to ERF (ΔF_{fsst}) is then given by the difference in ΔN_{fsst} between the simulations. The fSST method has less noise due to internal variability than the regression method. Nevertheless a 30-year fSST integration or 10 × 20-year regression ensemble needs to be conducted in order to reduce the 5–95% confidence range to 0.1 W m^{-2} (Forster et al., 2016), thus neither method is practical for quantifying the ERF of agents with forcing magnitudes of order 0.1 W m^{-2} or smaller. The internal variability in the fSST method can be further constrained by nudging winds towards a prescribed climatology (Kooperman et al., 2012). This allows the determination of the ERF of forcing agents with smaller magnitudes but excludes adjustments associated with circulation responses (Schmidt et al., 2018). There are insufficient studies to assess whether these circulation adjustments are significant.

Since the near-surface temperature change over land, ΔT_{land}, is not constrained in the fSST method, this response needs to be removed for consistency with the Section 7.1 definition. These changes in the near-surface temperature will also induce further responses in the tropospheric temperature and water vapour that should also be removed to conform with the physical definition of ERF. The radiative response to ΔT_{land} can be estimated through radiative transfer modelling in which a kernel, k, representing the change in net TOA radiative flux per change in unit near-surface temperature change over land (or an approximation using land surface temperature), is precomputed (Smith et al., 2018b; Richardson et al., 2019; Tang et al., 2019; Smith et al., 2020a). Thus ERF $\approx \Delta F_{\text{fsst}} - k\,\Delta T_{\text{land}}$. Since k is negative this means that ΔF_{fsst} underestimates the ERF. For 2×CO_2 this term is around 0.2 W m^{-2} (Smith et al., 2018b, 2020a). There have been estimates of the corrections due to tropospheric temperature and water vapour (Tang et al., 2019; Smith et al., 2020a) showing additional radiative responses of comparable magnitude to those directly from ΔT_{land}. An alternative to computing the response terms directly is to use the feedback parameter, α, (Hansen et al., 2005b; Sherwood et al., 2015; Tang et al., 2019). This gives approximately double the correction compared to the kernel approach (Tang et al., 2019). The response to land surface temperature change varies with location and even for GSAT change k is not expected to be the same as α (Section 7.4). One study where land-surface temperatures are constrained in a model (Andrews et al., 2021) finds this constraint adds +1.0 W m^{-2} to ΔF_{fsst} for 4×CO_2, thus confirming the need for a correction in calculations where this constraint is not applied. For this assessment the correction is conservatively based only on the direct radiative response kernel to ΔT_{land} as this has a strong theoretical basis to support it. While there is currently insufficient corroborating evidence to recommend including tropospheric temperature and water vapour corrections in this assessment, it is noted that the science is progressing rapidly on this topic.

TOA radiative flux changes due to the individual adjustments can be calculated by perturbing the meteorological fields in a climate model's radiative transfer scheme (partial radiative perturbation approach) (Colman, 2015; Mülmenstädt et al., 2019) or by using precomputed radiative kernels of sensitivities of the TOA radiation fluxes to changes in these fields (as done for near-surface temperature change above) (Vial et al., 2013; Zelinka et al., 2014; Zhang and Huang, 2014; Smith et al., 2018b, 2020a). The radiative kernel approach is easier to implement through post-processing of output from multiple ESMs, whereas it is recognized that the partial radiation perturbation approach gives a more accurate estimate of the adjustments within the setup of a single model and its own radiative transfer code. There is little difference between using a radiative kernel from the same or a different model when calculating the adjustment terms, except for stratospheric temperature adjustments where it is important to have sufficient vertical resolution in the stratosphere in the model used to derive the kernel (Smith et al., 2018b, 2020b).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

For comparison with offline radiative transfer calculations the SARFs can be approximated by removing the adjustment terms (apart from stratospheric temperature) from the ERFs using radiative kernels to quantify the adjustment for each meteorological variable. Kernel analysis by Chung and Soden (2015) suggested a large spread in CO_2 SARF across climate models, but their analysis was based on regressing variables in a coupled-ocean experiment rather than using a fSST approach which leads to a large spread due to natural variability (Forster et al., 2016). Adjustments computed from radiative kernels are shown for seven different climate drivers (using a fSST approach) in Figure 7.4. Table 7.2 shows the estimates of SARF, ΔF_{fsst} and ERF (corrected for land surface temperature change) for $2\times CO_2$ from the nine climate models analysed in Smith et al. (2018b). The SARF shows a smaller spread over previous studies (Pincus et al., 2016; Soden et al., 2018) and most estimates are within 10% of the multi-model mean and the assessment of $2\times CO_2$ SARF in Section 7.3.2 (3.75 W m^{-2}). It is not possible from these studies to determine how much of this reduction in spread is due to convergence in the model radiation schemes or the meteorological conditions of the model base states; nevertheless the level of agreement in this and earlier intercomparisons gives *medium confidence* in ESM's ability to represent radiative forcing from CO_2. The $4\times CO_2$ CMIP6 fSST experiments (Smith et al., 2020a) in Table 7.2 include ESMs with varying levels of complexity in aerosols and reactive gas chemistry. The CMIP6 experimental setup allows for further climate effects of CO_2 (including on aerosols and ozone) depending on model complexity. The chemical effects are adjustments to CO_2 but are not separable from the SARF in the diagnosis in Table 7.2. In these particular models, this leads to higher SARF than when only CO_2 varies, however there are insufficient studies to make a formal assessment of composition adjustments to CO_2.

[START TABLE 7.2 HERE]

Table 7.2: SARF, ΔF_{fsst}, and ERF diagnosed from ESMs for fSST CO_2 experiments. $2\times CO_2$ data taken from fixed atmospheric composition experiments (Smith et al., 2018b). $4\times CO_2$ data taken from CMIP6 experiments with interactive aerosols (and interactive gas phase chemistry in some) (Smith et al., 2020a). The radiative forcings from the $4\times CO_2$ experiments are scaled by 0.476 for comparison with $2\times CO_2$ (Meinshausen et al., 2020). SARF is approximated by removing the (non-stratospheric temperature) adjustment terms from the ERF. In Smith et al. (2018b) separation of temperature adjustments into tropospheric and stratospheric contributions is approximate based on a fixed tropopause of 100 hPa at the equator, varying linearly in latitude to 300 hPa at the poles. In Smith et al. (2020b) this separation is based on the model-diagnosed tropopause. ERF is approximated by removing the response to land surface temperature change from ΔF_{fsst}. The confidence range is based on the inter-model standard deviation.

[START FIGURE 7.4 HERE]

Figure 7.4: Radiative adjustments at top of atmosphere for seven different climate drivers as a proportion of forcing. Tropospheric temperature (orange), stratospheric temperature (yellow), water vapour (blue), surface albedo (green), clouds (grey) and the total adjustment (black) is shown. For the greenhouse gases (carbon dioxide, methane, nitrous oxide, CFC-12) the adjustments are expressed as a percentage of SARF, whereas for aerosol, solar and volcanic forcing they are expressed as a percentage of IRF. Land surface temperature response (outline red bar) is shown, but included in the definition of forcing. Data from Smith et al. (2018b) for carbon dioxide and methane, Smith et al. (2018b) and Gray et al. (2009) for solar, Hodnebrog et al. (2020b) for nitrous oxide and CFC-12, Smith et al. (2020a) for aerosol, and Marshall et al. (2020) for volcanic. Further details on data sources and processing are available in the chapter data table (Table 7.SM.14).

[END FIGURE 7.4 HERE]

ERFs have been found to yield more consistent values of GSAT change per unit forcing than SARF, i.e. α shows less variation across different forcing agents (Rotstayn and Penner, 2001; Shine et al., 2003; Hansen et al., 2005b; Marvel et al., 2016; Richardson et al., 2019). Having a consistent relationship between forcing and response is advantageous when making climate projections using simple models (Cross-Chapter Box 7.1) or emission-metrics (Section 7.6). The definition of ERF used in this assessment, which excludes the radiative response to land surface temperature changes, brings the α values into closer agreement than when SARF is used (Richardson et al., 2019), although for individual models there are still variations particularly for more geographically localised forcing agents. However, even for ERF, studies find that α is not identical across all forcing agents (Shindell, 2014; Shindell et al., 2015; Modak et al., 2018; Modak and Bala, 2019; Richardson et al., 2019). Section 7.4.4 discusses the effect of different SST response patterns on α. Analysis of the climate feedbacks (Kang and Xie, 2014; Gregory et al., 2016, 2020; Marvel et al., 2016; Duan et al., 2018; Persad and Caldeira, 2018; Stuecker et al., 2018; Krishnamohan et al., 2019) suggests a weaker feedback (i.e., less-negative α) and hence larger sensitivity for forcing of the higher latitudes (particularly the Northern Hemisphere). Nonetheless, as none of these variations are robust across models, the ratio of $1/\alpha$ from non-CO_2 forcing agents (with approximately global distributions) to that from doubling CO_2 is within 10% of unity.

In summary, this Report adopts an estimate of ERF based on the change in TOA radiative fluxes in the absence of GSAT changes. This allows for a theoretically cleaner separation between forcing and feedbacks

ACCEPTED VERSION SUBJECT TO FINAL EDITING

in terms of factors respectively unrelated and related to GSAT change (Box 7.1). ERF can be computed from prescribed SST and sea-ice experiments after removing the TOA energy budget change associated with the land surface temperature response. In this assessment this is removed using a kernel accounting only for the direct radiative effect of the land surface temperature response. To compare these results with sophisticated high spectral resolution radiative transfer models the individual tropospheric adjustment terms can be removed to leave the SARF. SARFs for $2\times CO_2$ calculated by ESMs from this method agree within 10% with the more sophisticated models. The new studies highlighted above suggest that physical feedback parameters computed within this framework have less variation across forcing agents. There is *high confidence* that an α based on ERF as defined here varies by less (less than variation 10% across a range of forcing agents with global distributions), than α based on SARF. For geographically localised forcing agents there are fewer studies and less agreement between them, resulting in *low confidence* that ERF is a suitable estimator of the resulting global mean near-surface temperature response.

7.3.2 Greenhouse Gases

High spectral resolution radiative transfer models provide the most accurate calculations of radiative perturbations due to greenhouse gases (GHGs) with errors in the IRF of less than 1% (Mlynczak et al., 2016; Pincus et al., 2020). They can calculate IRFs with no adjustments, or SARFs by accounting for the adjustment of stratospheric temperatures using a fixed dynamical heating. It is not possible with offline radiation models to account for other adjustments. The high resolution model calculations of SARF for carbon dioxide, methane and nitrous oxide have been updated since AR5, which were based on Myhre et al. (1998). The new calculations include the shortwave forcing from methane and updates to the water vapour continuum (increasing the total SARF of methane by 25%) and account for the absorption band overlaps between carbon dioxide and nitrous oxide (Etminan et al., 2016). The associated simplified expressions, from a re-fitting of the Etminan et al. (2016) results by Meinshausen et al. (2020), are given in Supplementary Table 7.SM.1. The shortwave contribution to the IRF of methane has been confirmed independently (Collins et al., 2018). Since they incorporate known missing effects we assess the new calculations as being a more appropriate representation than Myhre et al. (1998).

As described in Section 7.3.1, ERFs can be estimated using ESMs, however the radiation schemes in climate models are approximations to high spectral resolution radiative transfer models with variations and biases in results between the schemes (Pincus et al., 2015). Hence ESMs alone are not sufficient to establish ERF best estimates for the well-mixed GHGs (WMGHGs). This assessment therefore estimates ERFs from a combined approach that uses the SARF from radiative transfer models and adds the tropospheric adjustments derived from EMSs.

In AR5, the main information used to assess components of ERFs beyond SARF was from Vial et al. (2013) who found a near-zero non-stratospheric adjustment (without correcting for near-surface temperature changes over land) in $4\times CO_2$ CMIP5 model experiments, with an uncertainty of ±10% of the total CO_2 ERF. No calculations were available for other WMGHGs, so ERF was therefore assessed to be approximately equal to SARF (within 10%) for all WMGHGs.

The effect of WMGHGs in ESMs can extend beyond their direct radiative effects to include effects on ozone and aerosol chemistry and natural emissions of ozone and aerosol precursors, and in the case of CO_2 to vegetation cover through physiological effects. In some cases these can have significant effects on the overall radiative budget changes from perturbing WMGHGs within ESMs (Myhre et al., 2013b; Zarakas et al., 2020; O'Connor et al., 2021; Thornhill et al., 2021a). These composition adjustments are further discussed in Chapter 6 (Section 6.4.2).

7.3.2.1 Carbon Dioxide

The SARF for CO_2 has been slightly revised due to updates to spectroscopic data and inclusion of the absorption band overlaps between N_2O and CO_2 (Etminan et al., 2016). The formulae fitting to the Etminan

ACCEPTED VERSION SUBJECT TO FINAL EDITING

et al. (2016) results in Meinshausen et al. (2020) are used. This increases the SARF due to doubling CO_2 slightly from 3.71 W m^{-2} in AR5 to 3.75 W m^{-2}. Tropospheric responses to CO_2 in fSST experiments have been found to lead to an approximate balance in their radiative effects between an increased radiative forcing due to water vapour, cloud and surface albedo adjustments and a decrease due to increased tropospheric temperature and land surface temperature response (Vial et al., 2013; Zhang and Huang, 2014; Smith et al., 2018b, 2020a; Table 7.3). The ΔF_{fsst} includes any effects represented within the ESMs on tropospheric adjustments due to changes in evapotranspiration or leaf area (mainly affecting surface and boundary layer temperature, low cloud amount and albedo) from the CO_2-physiological effects (Doutriaux-Boucher et al., 2009; Cao et al., 2010; Richardson et al., 2018b). The effect on surface temperature (negative longwave response) is consistent with the expected physiological responses and needs to be removed for consistency with the ERF definition. The split between surface and tropospheric temperature responses was not reported in Vial et al. (2013) or Zhang and Huang (2014) but the total of surface and tropospheric temperature response agrees with Smith et al. (2018b, 2020b) giving *medium confidence* in this decomposition. Doutriaux-Boucher et al. (2009) and Andrews et al. (2021) (using the same land surface model) find a 13% and 10% increase respectively in ERF due to the physiological responses to CO_2. The physiological adjustments are therefore assessed to make a substantial contribution to the overall tropospheric adjustment for CO_2 (*high confidence*), but there is insufficient evidence to provide a quantification of the split between physiological and thermodynamic adjustments. These forcing adjustments due to the effects of CO_2 on plant physiology differ from the biogeophysical feedbacks due to the effects of temperature changes on vegetation discussed in Section 7.4.2.5. The adjustment is assumed to scale with the SARF in the absence of evidence for non-linearity. The tropospheric adjustment is assessed from Table 7.3 to be +5% of the SARF with an uncertainty of 5%, which is added to the Meinshausen et al. (2020) formula for SARF. Due to the agreement between the studies and the understanding of the physical mechanisms there is *medium confidence* in the mechanisms underpinning the tropospheric adjustment, but *low confidence* in its magnitude.

[START TABLE 7.3 HERE]

Table 7.3: Adjustments to the TOA CO_2 forcing due to changes in stratospheric temperature, surface and tropospheric temperatures, water vapour, clouds and surface albedo, as a fraction of the SARF. ERF is defined in this report as excluding the surface temperature response.

Percentage of SARF	Surface temp	Trop. temp	Strat. temp	Surface albedo	Water vapour	Clouds	Troposphere (inc. surface)	Troposphere (excl. surface)
Vial et al. (2013)	–20%			2%	6%	11%	–1%	
Zhang and Huang (2014)	–23%		26%		6%	16%	–1%	
Smith et al. (2018b)	–6%	–16%	30%	3%	6%	12%	–1%	+5%
Smith et al. (2020b)	–6%	–15%	35%	3%	6%	15%	+3%	+9%

[END TABLE 7.3 HERE]

The ERF from doubling CO_2 ($2\times CO_2$) from the 1750 level (278 ppm Chapter 2, Section 2.2.3.3) is assessed to be 3.93 ± 0.47 W m^{-2} (*high confidence*). Its assessed components are given in Table 7.4. The combined spectroscopic and radiative transfer modelling uncertainties give an uncertainty in the CO_2 SARF of around 10% or less (Etminan et al., 2016; Mlynczak et al., 2016). The overall uncertainty in CO_2 ERF is assessed as ±12%, as the more uncertain adjustments only account for a small fraction of the ERF (Table 7.3). The $2\times CO_2$ ERF estimate is 0.2 W m^{-2} larger than using the AR5 formula (Myhre et al., 2013b) due to the combined effects of tropospheric adjustments which were assumed to be zero in AR5. CO_2 concentrations have increased from 278 ppm in 1750 to 410 ppm in 2019 (Chapter 2, Section 2.2.3.3). The historical ERF

ACCEPTED VERSION SUBJECT TO FINAL EDITING

estimate from CO_2 is revised upwards from the AR5 value of 1.82 ± 0.38 W m^{-2} (1750 to 2011) to 2.16 ±0.26 W m^{-2} (1750 to 2019) in this assessment, from a combination of the revisions described above (0.06 W m^{-2}) and the 19 ppm rise in atmospheric concentrations between 2011 and 2019 (0.27 W m^{-2}). The ESM estimates of 2×CO_2 ERF (Table 7.2) lie within ±12% of the assessed value (apart from CESM2). The definition of ERF can also include further physiological effects for instance on dust, natural fires and biogenic emissions from the land and ocean, but these are not typically included in the modelling set up for 2×CO_2 ERF.

[START TABLE 7.4 HERE]

Table 7.4: Assessed ERF, SARF and tropospheric adjustments to 2×CO_2 change since preindustrial times compared to the AR5 assessed range (Myhre et al., 2013b). Adjustments are due to changes in tropospheric temperatures, water vapour, clouds and surface albedo and land cover and are taken from Smith et al. (2018b) and assessed as a percentage of SARF (Table 7.3). Uncertainties are based on multi-model spread in Smith et al. (2018b). Note some of the uncertainties are anticorrelated, which means that they do not sum linearly.

2×CO_2 forcing	AR5 SARF/ ERF	SARF (W m^{-2})	Tropospheric temperature adjustment (W m^{-2})	Water vapour adjustment (W m^{-2})	Cloud adjustment (W m^{-2})	Surface albedo and land cover adjustment (W m^{-2})	Total tropospheric adjustment (W m^{-2})	ERF (W m^{-2})
2×CO_2 ERF components	3.71	3.75	–0.60	0.22	0.45	0.11	0.18	3.93
5%–95% uncertainty ranges as percentage of ERF	10% (SARF) 20% (ERF)	<10%	±6%	±4%	±7%	±2%	±7%	±12%

[END TABLE 7.4 HERE]

7.3.2.2 Methane

The SARF for methane (CH_4) has been substantially increased due to updates to spectroscopic data and inclusion of the shortwave absorption (Etminan et al., 2016). Adjustments have been calculated in nine climate models by Smith et al. (2018b). Since CH_4 is found to absorb in the shortwave near infrared, only adjustments from those models including this absorption are taken into account. For these models the adjustments act to reduce the ERF because the shortwave absorption leads to tropospheric heating and reductions in upper tropospheric cloud amounts. The adjustment is –14% ± 15% which counteracts much of the increase in SARF identified by Etminan et al. (2016). Modak et al. (2018) also found negative forcing adjustments from a methane perturbation including shortwave absorption in the NCAR CAM5 model, in agreement with the above assessment. The uncertainty in the shortwave component leads to a higher radiative modelling uncertainty (14%) than for CO_2 (Etminan et al., 2016). When combined with the uncertainty in the adjustment, this gives an overall uncertainty of ± 20%. There is *high confidence* in the spectroscopic revision but only *medium confidence* in the adjustment modification. CH_4 concentrations have increased from 729 ppb in 1750 to 1866 ppb in 2019 (Chapter 2, Section 2.2.3.3). The historical ERF estimate from AR5 of 0.48 ± 0.10 W m^{-2} (1750 to 2011) is revised to 0.54 ± 0.11 W m^{-2} (1750 to 2019) in this assessment from a combination of spectroscopic radiative efficiency revisions (+0.12 W m^{-2}), adjustments (–0.08 W m^{-2}) and the 63 ppb rise in atmospheric CH_4 concentrations between 2011 and 2019 (+0.03 W m^{-2}). As the adjustments are assessed to be small, there is *high confidence* in the overall assessment of ERF from methane. Increased methane leads to tropospheric ozone production and increased stratospheric water vapour, so that an attribution of forcing to methane emissions gives a larger effect than that directly from the methane concentration itself. This is discussed in detail in Chapter 6, Section 6.4.2 and

ACCEPTED VERSION SUBJECT TO FINAL EDITING

shown in Figure 6.12.

7.3.2.3 Nitrous oxide

The tropospheric adjustments to nitrous oxide (N_2O) have been calculated from 5 ESMs as 7% ± 13% of the SARF (Hodnebrog et al., 2020b). This value is therefore taken as the assessed adjustment, but with *low confidence*. The radiative modelling uncertainty is ± 10% (Etminan et al., 2016), giving an overall uncertainty of ± 16%. Nitrous oxide concentrations have increased from 270 ppb in 1750 to 332 ppb in 2019 (Chapter 2, Section 2.2.3.3). The historical ERF estimate from N_2O is revised upwards from 0.17 ± 0.06 W m^{-2} (1750 to 2011) in AR5 to 0.21 ± 0.03 W m^{-2} (1750 to 2019) in this assessment, of which 0.02 W m^{-2} is due to the 7 ppb increase in concentrations, and 0.02 W m^{-2} to the tropospheric adjustment. As the adjustments are assessed to be small there remains *high confidence* in the overall assessment.

Increased nitrous oxide leads to ozone depletion in the upper stratosphere which will make a positive contribution to the direct ERF here (Chapter 6, Section 6.4.2, Figure 6.12) when considering emission-based estimates of ERF.

7.3.2.4 Halogenated species

The stratospheric-temperature adjusted radiative efficiencies (SARF per ppb increase in concentration) for halogenated compounds are reviewed extensively in Hodnebrog et al. (2020a), an update to those used in AR5. Many halogenated compounds have lifetimes short enough that they can be considered short-lived climate forcers (Table 6.1). As such, they are not completely "well-mixed" and their vertical distributions are taken into account when determining their radiative efficiencies. The WMO (World Meteorological Organization, 2018) updated the lifetimes of many halogenated compounds and these were used in Hodnebrog et al. (2020a).

The tropospheric adjustments to chlorofluorocarbons (CFCs), specifically CFC-11 and CFC-12, have been quantified as 13% ± 10% and 12% ± 14% of the SARF respectively (Hodnebrog et al., 2020b). The assessed adjustment to CFCs is therefore 12 % ± 13% with *low confidence* due to the lack of corroborating studies. There have been no calculations for other halogenated species so for these the tropospheric adjustments are therefore assumed to be 0 ± 13% with *low confidence.* The radiative modelling uncertainties are 14% and 24% for compounds with lifetimes greater than and less than 5 years respectively (Hodnebrog et al., 2020a). The overall uncertainty in the ERFs of halogenated compounds is therefore assessed to be 19% and 26% depending on the lifetime. The ERF from CFCs is slowly decreasing, but this is compensated for by the increased forcing from the replacement species (HCFCs and HFCs). The ERF from HFCs has increased by 0.028 ± 0.05 W m^{-2}. Thus, the concentration changes mean that the total ERF from halogenated compounds has increased since AR5 from 0.360 ± 0.036 W m^{-2} to 0.408 ± 0.078 W m^{-2} (Table 7.5). Of this 0.034 W m^{-2} is due to increased radiative efficiencies and tropospheric adjustments, and 0.014 W m^{-2} due to increases in concentrations. As the adjustments are assessed to be small there remains *high confidence* in the overall assessment.

Halogenated compounds containing chlorine and bromine lead to ozone depletion in the stratosphere which will reduce the associated ERF (Morgenstern et al., 2020). Chapter 6, Section 6.4 and Figure 6.12 assess the ERF contributions due to the chemical effects of reactive gases.

7.3.2.5 Ozone

Estimates of the pre-industrial to present-day tropospheric ozone radiative forcing are based entirely on models. The lack of pre-industrial ozone measurements prevents an observational determination. There have been limited studies of ozone ERFs (MacIntosh et al., 2016; Xie et al., 2016; Skeie et al., 2020). Skeie et al. (2020) found little net contribution to the ERF from tropospheric adjustment terms for 1850-2000 change in

ACCEPTED VERSION SUBJECT TO FINAL EDITING

ozone (tropospheric and stratospheric ozone combined), although MacIntosh et al. (2016) suggested that increases in stratospheric or upper tropospheric ozone reduces high cloud and increases low cloud, whereas an increase in lower tropospheric ozone reduces low cloud. Further studies suggest that changes in circulation due to decreases in stratospheric ozone affect Southern Hemisphere clouds and the atmospheric levels of sea salt aerosol that would contribute additional adjustments, possibly of comparable magnitude to the SARF from stratospheric ozone depletion (Grise et al., 2013, 2014, Xia et al., 2016, 2020). ESM responses to changes in ozone depleting substances (ODS) in CMIP6 show a much more negative ERF than would be expected from offline calculations of SARF (Morgenstern et al., 2020; Thornhill et al., 2021b) again suggesting a negative contribution from adjustments. However there is insufficient evidence available to quantify this effect.

Without sufficient information to assess whether the ERFs differ from SARF, this assessment relies on offline radiative transfer calculations of SARF for both tropospheric and stratospheric ozone. Checa-Garcia et al. (2018) found SARF of 0.30 W m^{-2} for changes in ozone (1850–1860 to 2009–2014). These were based on precursor emissions and ODS concentrations from the Coupled Chemistry Model Initiative (CCMI) project (Morgenstern et al., 2017). Skeie et al. (2020) calculated an ozone SARF of 0.41 ± 0.12 W m^{-2} (1850 to 2010) (from five climate models and one chemistry transport model) using CMIP6 precursor emissions and ODS concentrations (excluding models without fully interactive ozone chemistry and one model with excessive ozone depletion). The ozone precursor emissions are higher in CMIP6 than in CCMI which explains much of the increase compared to Checa-Garcia et al. (2018).

Previous assessments have split the ozone forcing into tropospheric and stratospheric components. This does not correspond to the division between ozone production and ozone depletion and is sensitive to the choice of tropopause (Myhre et al., 2013b) (*high confidence*). The contributions to total SARF in CMIP6 (Skeie et al., 2020) are 0.39 ± 0.07 and 0.02 ± 0.07 W m^{-2} for troposphere and stratosphere respectively (using a 150 ppb ozone tropopause definition). This small positive (but with uncertainty encompassing negative values) stratospheric ozone SARF is due to contributions from ozone precursors to lower stratospheric ozone and some of the CMIP6 models showing ozone depletion in the upper stratosphere, where depletion contributes a positive radiative forcing *(medium confidence)*.

As there is insufficient evidence to quantify adjustments, for total ozone the assessed central estimate for ERF is assumed to be equal to SARF (*low confidence*) and follows Skeie et al. (2020) since that study uses the most recent emission data. The dataset is extended over the entire historical period following Skeie et al. (2020) with a SARF for 1750 to 1850 of 0.03 W m^{-2} and for 2010 to 2018 of 0.03 W m^{-2}, to give 0.47 [0.24 to 0.70] W m^{-2} for 1750 to 2019. This maintains the 50% uncertainty (5%–95% range) from AR5 which is largely due to the uncertainty in pre-industrial emissions (Rowlinson et al., 2020). There also *high confidence* that this range includes uncertainty due to the adjustments. The CMIP6 SARF is more positive than the AR5 value of 0.31 W m^{-2} for the period 1850 to 2011 (Myhre et al., 2013b) which was based on the Atmospheric Chemistry and Climate Intercomparison Project (ACCMIP) (Shindell et al., 2013). The assessment is sensitive to the assumptions on precursor emissions used to drive the models, which are larger in CMIP6 than ACCMIP.

In summary, although there is insufficient evidence to quantify adjustments, there is *high confidence* in the assessed range of ERF for ozone changes over the 1750 to 2019 period, giving an assessed ERF of 0.47 [0.24 to 0.70] W m^{-2}.

7.3.2.6 Stratospheric water vapour

This section considers direct anthropogenic effects on stratospheric water vapour by oxidation of methane. Since AR5 the SARF from methane-induced stratospheric water vapour changes has been calculated in two models (Winterstein et al., 2019; O'Connor et al., 2021), both corresponding to 0.09 W m^{-2} (1850 to 2014, by scaling the Winterstein et al., 2019 study). This is marginally larger than the AR5 assessed value of 0.07±0.05 W m^{-2} (Myhre et al., 2013b). However, O'Connor et al. (2021) found the ERF to be approximately zero due to a negative cloud adjustment. Wang and Huang (2020) quantified the adjustment

ACCEPTED VERSION SUBJECT TO FINAL EDITING

terms to a stratospheric water vapour change equivalent to that from a $2\times CO_2$ warming (which has different vertical profile, though also largest in the lower stratosphere). They found that the ERF was less than 50% of the SARF due to high cloud decrease and upper tropospheric warming. The assessed ERF is therefore 0.05±0.05 W m^{-2} with a lower limit reduced to zero and the central value and upper limit reduced to allow for adjustment terms. This still encompasses the two recent SARF studies. There is *medium confidence* in the SARF from agreement with the recent studies and AR5. There is *low confidence* in the adjustment terms.

Stratospheric water vapour may also change as an adjustment to species that warm or cool the upper troposphere-lower stratosphere region (Forster and Joshi, 2005; Stuber et al., 2005), in which case it should be included as part of the ERF for that compound. Changes in GSAT are also associated with changes in stratospheric water vapour as part of the water vapour climate feedback (Section 7.4.2.2).

7.3.2.7 Synthesis

The GHGs (excluding ozone and stratospheric water vapour) ERF over 1750 to 2019 is assessed to be 3.32 ± 0.29 W m^{-2}. It has increased by 0.49 W m^{-2} compared to AR5 (reference year 2011) *(high confidence)*. Most of this has been due to an increase in CO_2 concentration since 2011 [0.27 ± 0.03 W m^{-2}], with concentration increases in CH_4, N_2O and halogenated compounds adding 0.02, 0.02 and 0.01 W m^{-2} respectively (Table 7.5). Changes in the radiative efficiencies (including adjustments) of CO_2, CH_4, N_2O and halogenated compounds have increased the ERF by an additional 0.15 W m^{-2} compared to the AR5 values (*high confidence*). Note that the ERFs in this section do not include chemical effects of GHGs on production or destruction of ozone or aerosol formation (see Chapter 6, Section 6.2.2). The ERF for ozone is considerably increased compared to AR5 due to an increase in the assumed ozone precursor emissions in CMIP6 compared to CMIP5, and better accounting for the effects of both ozone precursors and ODSs in the stratosphere. The ERF for stratospheric water vapour is slightly reduced. The combined ERF from ozone and stratospheric water vapour has increased since AR5 by 0.10 ± 0.50 W m^{-2} (*high confidence*), although the uncertainty ranges still include the AR5 values.

[START TABLE 7.5 HERE]

Table 7.5: Present-day mole fractions in ppt (pmol mol^{-1}) (except where specified) and ERF (in W m^{-2}) for the WMGHGs. Data taken from Chapter 2, Section 2.2.3. The data for 2011 (the time of the AR5 estimates) are also shown. Some of the concentrations vary slightly from those reported in AR5 owing to averaging different data sources. Individual species are reported where 1750-2019 ERF is at least 0.001 W m^{-2}. Radiative efficiencies for the minor gases are given in Supplementary Table 7.SM.7. Uncertainties in the ERF for all gases are dominated by the uncertainties in the radiative efficiencies. Tabulated global mixing ratios of all well mixed GHGs and ERFs from 1750-2019 are provided in Annex III.

	Concentration				ERF with respect to 1850		ERF with respect to 1750

7.3.3 Aerosols

Anthropogenic activity, and particularly burning of biomass and fossil fuels, has led to a substantial increase in emissions of aerosols and their precursors, and thus to increased atmospheric aerosol concentrations since pre-industrial times (Chapter 2, Section 2.2.6 and Figure 2.9; Chapter 6, Section 6.3.5). This is particularly true for sulphate and carbonaceous aerosols (Chapter 6, Section 6.3.5). This has in turn led to changes in the scattering and absorption of incoming solar radiation, and also affected cloud micro- and macro-physics and thus cloud radiative properties. Aerosol changes are heterogeneous in both space and time and have impacted not just Earth's radiative energy budget but also air quality (Chapter 6, Section 6.1.1 and 6.6.2). Here, the assessment is focused exclusively on the global mean effects of aerosols on Earth's energy budget, while regional changes and changes associated with individual aerosol compounds are assessed in Chapter 6, Sections 6.4.1 and 6.4.2.

Consistent with the terminology introduced in Box 7.1, the ERF due to changes from direct aerosol-radiation interactions (ERFari) is equal to the sum of the instantaneous TOA radiation change (IRFari) and the subsequent adjustments. Likewise, the ERF following interactions between anthropogenic aerosols and clouds (ERFaci, referred to as "indirect aerosol effects" in previous assessment reports) can be divided into an instantaneous forcing component (IRFaci) due to changes in cloud droplet (and indirectly also ice crystal) number concentrations and sizes, and the subsequent adjustments of cloud water content or extent. While these changes are thought to be induced primarily by changes in the abundance of cloud condensation nuclei (CCN), a change in the number of ice nucleating particles (INPs) in the atmosphere may also have occurred, and thereby contributed to ERFaci by affecting properties of mixed-phase and cirrus (ice) clouds. In the following, an assessment of IRFari and ERFari (Section 7.3.3.1) focusing on observation-based (Section 7.3.3.1.1) as well as model-based (Section 7.3.3.1.2) evidence is presented. The same lines of evidence are presented for IRFaci and ERFaci in Section 7.3.3.2. These lines of evidence are then compared with TOA energy budget constraints on the total aerosol ERF (Section 7.3.3.3) before an overall assessment of the total aerosol ERF is given in Section 7.3.3.4. For the model-based evidence, all estimates are generally valid for 2014 relative to 1750 (the time period spanned by CMIP6 historical simulations), while for observation-based evidence the assessed studies use slightly different end points, but they all generally fall within a decade (2010-2020).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

7.3.3.1 Aerosol-radiation interactions

Since AR5, deeper understanding of the processes that govern aerosol radiative properties, and thus IRFari, has emerged. Combined with new insights into adjustments to aerosol forcing, this progress has informed new observation- and model-based estimates of ERFari and associated uncertainties.

7.3.3.1.1 Observation-based lines of evidence

Estimating IRFari requires an estimate of industrial-era changes in Aerosol Optical Depth (AOD) and absorption AOD, which are often taken from global aerosol model simulations. Since AR5, updates to methods of estimating IRFari based on aerosol remote sensing or data-assimilated reanalyses of atmospheric composition have been published. Ma et al. (2014) applied the method of Quaas et al. (2008) to updated broadband radiative flux measurements from CERES, MODIS-retrieved AODs, and modelled anthropogenic aerosol fractions to find a clear-sky IRFari of −0.6 W m^{-2}. This would translate into an all-sky estimate of about −0.3 W m^{-2} based on the clear-to-all-sky ratio implied by Kinne (2019). Rémy et al. (2018) applied the methods of Bellouin et al. (2013b) to the reanalysis by the Copernicus Atmosphere Monitoring Service, which assimilates MODIS total AOD. Their estimate of IRFari varies between −0.5 W m^{-2} and −0.6 W m^{-2} over the period 2003–2018, and they attribute those relatively small variations to variability in biomass-burning activity. Kinne (2019) provided updated monthly total AOD and absorption AOD climatologies, obtained by blending multi-model averages with ground-based sun-photometer retrievals, to find a best estimate of IRFari of −0.4 W m^{-2}. The updated IRFari estimates above are all scattered around the midpoint of the IRFari range of −0.35 ± 0.5 W m^{-2} assessed by AR5 (Boucher et al., 2013).

The more negative estimate of Rémy et al. (2018) is due to neglecting a small positive contribution from absorbing aerosols above clouds and obtaining a larger anthropogenic fraction than Kinne (2019). Rémy et al. (2018) also did not update their assumptions on black carbon anthropogenic fraction and its contribution to absorption to reflect recent downward revisions (Section 7.3.3.1.2). Kinne (2019) made those revisions, so more weight is given to that study to assess the central estimate of satellite-based IRFari to be only slightly stronger than reported in AR5 at –0.4 W m^{-2}. While uncertainties in the anthropogenic fraction of total AOD remain, improved knowledge of anthropogenic absorption results in a slightly narrower *very likely* range here than in AR5. The assessed best estimate and *very likely* IRFari range from observation-based evidence is therefore –0.4 ± 0.4 W m^{-2} , but with *medium confidence* due to the limited number of studies available.

7.3.3.1.2 Model-based lines of evidence

While observation-based evidence can be used to estimate IRFari, global climate models are needed to calculate the associated adjustments and the resulting ERFari, using the methods described in Section 7.3.1. A range of developments since AR5 affect model-based estimates of IRFari. Global emissions of most major aerosol compounds and their precursors are found to be higher in the current inventories, and with increasing trends. Emissions of the sulphate precursor SO_2 are a notable exception; they are similar to those used in AR5 and approximately time-constant in recent decades (Hoesly et al., 2018). Myhre et al. (2017) showed, in a multi-model experiment, that the net result of these revised emissions is an IRFari trend that is relatively flat in recent years (post-2000), a finding confirmed by a single-model study by Paulot et al. (2018).

In AR5, the assessment of the black carbon (BC) contribution to IRFari was markedly strengthened in confidence by the review by Bond et al. (2013), where a key finding was a perceived model underestimate of atmospheric absorption when compared to Aeronet observations (Boucher et al., 2013). This assessment has since been revised considering new knowledge on the effect of the temporal resolution of emission inventories (Wang et al., 2016), the representativeness of Aeronet sites (Wang et al., 2018), issues with comparing absorption retrieval to models (Andrews et al., 2017a), and the ageing (Peng et al., 2016), lifetime (Lund et al., 2018b) and average optical parameters (Zanatta et al., 2016) of BC. Consistent with these updates, Lund et al. (2018a) estimated the net IRFari in 2014 (relative to 1750) to be –0.17 W m^{-2}, using CEDS emissions (Hoesly et al., 2018) as input to a chemical transport model. They attributed the weaker estimate relative to AR5 (–0.35 ± 0.5 W m^{-2}; Myhre et al., 2013a) to stronger absorption by organic aerosol,

ACCEPTED VERSION SUBJECT TO FINAL EDITING

updated parameterization of BC absorption, and slightly reduced sulphate cooling. Broadly consistent with Lund et al. (2018a), another single-model study by Petersik et al. (2018) estimated an IRFari of –0.19 W m^{-2}. Another single-model study by Lurton et al. (2020) reported a more negative estimate at –0.38 W m^{-2}, but is given less weight here because the model lacked interactive aerosols and instead used prescribed climatological aerosol concentrations.

The above estimates support a less negative central estimate and a slightly narrower range compared to those reported for IRFari from ESMs in AR5 of –0.35 [–0.6 to –0.13] W m^{-2}. The assessed central estimate and *very likely* IRFari range from model-based evidence alone is therefore –0.2 ± 0.2 W m^{-2} for 2014 relative to 1750, with *medium confidence* due to the limited number of studies available. Revisions due to stronger organic aerosol absorption, further developed BC parameterizations and somewhat reduced sulphate emissions in recent years.

Since AR5 considerable progress has been made in the understanding of adjustments in response to a wide range of climate forcings, as discussed in Section 7.3.1. The adjustments in ERFari are principally caused by cloud changes, but also by lapse rate and atmospheric water vapour changes, all mainly associated with absorbing aerosols like BC. Stjern et al. (2017) found that for BC, about 30% of the (positive) IRFari is offset by adjustments of clouds (specifically, an increase in low clouds and decrease in high clouds) and lapse rate, by analysing simulations by five Precipitation Driver Response Model Intercomparison Project (PDRMIP) models. Smith et al. (2018b) considered more models participating in PDRMIP and suggested that about half the IRFari was offset by adjustments for BC, a finding generally supported by single-model studies (Takemura and Suzuki, 2019; Zhao and Suzuki, 2019). Thornhill et al. (2021b) also reported a negative adjustment for BC based on AerChemMIP (Collins et al., 2017) but found it to be somewhat smaller in magnitude than those reported in Smith et al. (2018b) and Stjern et al. (2017). In contrast, Allen et al. (2019) found a positive adjustment for BC and suggested that most models simulate negative adjustment for BC because of a misrepresentation of aerosol atmospheric heating profiles.

Zelinka et al. (2014) used the Approximate Partial Radiation Perturbation technique to quantify the ERFari in 2000 relative to 1860 in nine CMIP5 models; they estimated the ERFari (accounting for a small contribution from longwave radiation) to be –0.27 ± 0.35 W m^{-2}. However, it should be noted that in Zelinka et al. (2014) adjustments of clouds caused by absorbing aerosols through changes in the thermal structure of the atmosphere (termed the semidirect effect of aerosols in AR5) are not included in ERFari but in ERFaci. The corresponding estimate emerging from the Radiative Forcing Model Intercomparison Project (RFMIP, Pincus et al., 2016) is –0.25 ± 0.40 W m^{-2} (Smith et al., 2020a), which is generally supported by single-model studies published post-AR5 (Zhang et al., 2016; Fiedler et al., 2017; Nazarenko et al., 2017; Zhou et al., 2017c; Grandey et al., 2018; Zhou et al., 2018b). A 5% inflation is applied to the CMIP5 and CMIP6 fixed-SST derived estimates of ERFari from Zelinka et al. (2014) and (Smith et al., 2020a) to account for land surface cooling (Table 7.6). Based on the above, ERFari from model-based evidence is assessed to be –0.25 ± 0.25 W m^{-2}.

7.3.3.1.3 Overall assessment of IRFari and ERFari

The observation-based assessment of IRFari of –0.4 ± 0.4 W m^{-2} and the corresponding model-based assessment of –0.2 ± 0.2 W m^{-2} can be compared to the range of –0.45 W m^{-2} to –0.05 W m^{-2} that emerged from a comprehensive review in which an observation-based estimate of anthropogenic AOD was combined with model-derived ranges for all relevant aerosol radiative properties (Bellouin et al., 2019). Based on the above, IRFari is assessed to be –0.25 ± 0.2 W m^{-2} (*medium confidence*).

ERFari from model-based evidence is –0.25 ± 0.25 W m^{-2}, which suggests a small negative adjustment relative to the model-based IRFari estimate, consistent with the literature discussed in 7.3.3.1.2. Adding this small adjustment to our assessed IRFari estimate of –0.25 W m^{-2}, and accounting for additional uncertainty in the adjustments, ERFari is assessed to –0.3 ± 0.3 (*medium confidence*). This assessment is consistent with the 5% to 95 % confidence range for ERFari in Bellouin et al. (2019) of –0.71 to –0.14 W m^{-2}, and notably implies that it is *very likely* that ERFari is negative. Differences relative to Bellouin et al. (2019) reflect the range of estimates in Table 7.6 and the fact that a more negative ERFari than -0.6 W m^{-2} would require

ACCEPTED VERSION SUBJECT TO FINAL EDITING

adjustments that considerably augment the assessed IRFari, which is not supported by the assessed literature.

[START TABLE 7.6 HERE]

Table 7.6: Present-day ERF due to changes in aerosol-radiation interactions (ERFari) and changes in aerosol-cloud interactions (ERFaci), and total aerosol ERF (ERFari+aci) from GCM CMIP6 (2014 relative to 1850) (Smith et al., 2020a and later model results) and CMIP5 (year 2000 relative to 1860) (Zelinka et al., 2014). CMIP6 results are simulated as part of RFMIP (Pincus et al., 2016). An additional 5% is applied to the CMIP5 and CMIP6 model results to account for land-surface cooling (Smith et al., 2020b; Figure 7.4).

7.3.3.2 Aerosol-cloud interactions

Anthropogenic aerosol particles primarily affect water clouds by serving as additional cloud condensation nuclei (CCN) and thus increasing cloud drop number concentration (N_d) (Twomey, 1959). Increasing N_d while holding liquid water content constant reduces cloud drop effective radius (r_e), increases the cloud albedo, and induces an instantaneous negative radiative forcing (IRFaci). The clouds are thought to subsequently adjust by a slowing of the drop coalescence rate, thereby delaying or suppressing rainfall. Rain generally reduces cloud lifetime and thereby liquid water path (LWP, i.e., the vertically integrated cloud water) and/or cloud fractional coverage (Cf) (Albrecht, 1989), thus any aerosol-induced rain delay or suppression would be expected to increase LWP and/or Cf. Such adjustments could potentially lead to an ERFaci considerably larger in magnitude than the IRFaci alone. However, adding aerosols to non-

ACCEPTED VERSION SUBJECT TO FINAL EDITING

precipitating clouds has been observed to have the opposite effect (i.e., a reduction in LWP and/or Cf) (Lebsock et al., 2008; Christensen and Stephens, 2011). These findings have been explained by enhanced evaporation of the smaller droplets in the aerosol-enriched environments, and resultant enhanced mixing with ambient air, leading to cloud dispersal.

A small subset of aerosols can also serve as ice nucleating particles (INPs) that initiate the ice phase in supercooled water clouds, and thereby alter cloud radiative properties and/or lifetimes. However, the ability of anthropogenic aerosols (specifically BC) to serve as INPs in mixed-phase clouds has been found to be negligible in recent laboratory studies (e.g., Vergara-Temprado et al. (2018)). No assessment of the contribution to ERFaci from cloud phase changes induced by anthropogenic INPs will therefore be presented.

In ice (cirrus) clouds (cloud temperatures less than –40° C), INPs can initiate ice crystal formation at relative humidity much lower than that required for droplets to freeze spontaneously. Anthropogenic INPs can thereby influence ice crystal numbers and thus cirrus cloud radiative properties. At cirrus temperatures, certain types of BC have in fact been demonstrated to act as INPs in laboratory studies (Ullrich et al., 2017; Mahrt et al., 2018), suggesting a non-negligible anthropogenic contribution to INPs in cirrus clouds. Furthermore, anthropogenic changes to drop number also alter the number of droplets available for spontaneous freezing, thus representing a second pathway through which anthropogenic emissions could affect cirrus clouds.

7.3.3.2.1 Observation-based evidence

Since AR5, the analysis of observations to investigate aerosol-cloud interactions has progressed along several axes: (i) The framework of forcing and adjustments introduced rigorously in AR5 has helped better categorize studies; (ii) the literature assessing statistical relationships between aerosol- and cloud in satellite retrievals has grown, and retrieval uncertainties are better characterized; (iii) advances have been made to infer causality in aerosol-cloud relationships.

[START TABLE 7.7 HERE]

Table 7.7: Studies quantifying aspects of the global ERFaci that are mainly based on satellite retrievals and were published since AR5. All forcings/adjustments as global annual mean values in W m^{-2}. Most studies split the ERFaci into IRFaci and adjustments in LWP and cloud fraction separately. All published studies only considered liquid clouds. Some studies assessed the IRFaci and the LWP adjustment together and called this "intrinsic forcing"(Christensen et al., 2017) and the cloud fraction adjustment "extrinsic forcing". Published uncertainty ranges are converted to 5%–95 % confidence intervals, and "n/a" indicates that the study did not provide an estimate for the relevant IRF/ERF.

[END TABLE 7.7 HERE]

In AR5 the statistical relationship between cloud microphysical properties and aerosol index (AI; AOD multiplied by Ångström exponent) was used to make inferences about IRFaci were assessed alongside other studies which related cloud quantities to AOD. However, it is now well-documented that the latter approach leads to low estimates of IRFaci since AOD is a poor proxy for cloud-base CCN (Penner et al., 2011; Stier, 2016). Gryspeerdt et al. (2017) demonstrated that the statistical relationship between droplet concentration and AOD leads to an inferred IRFaci that is underestimated by at least 30%, while the use of AI leads to estimates of IRFaci to within ±20%, if the anthropogenic perturbation of AI is known.

Further, studies assessed in AR5 mostly investigated linear relationships between cloud droplet concentration and aerosol (Boucher et al., 2013). Since in most cases the relationships are not linear, this leads to a bias (Gryspeerdt et al., 2016). Several studies did not relate cloud droplet concentration, but cloud droplet effective radius to the aerosol (Brenguier et al., 2000). This is problematic since then, in order to infer IRFaci, stratification by cloud LWP is required (McComiskey and Feingold, 2012). Where LWP positively co-varies with aerosol retrievals (which is often the case), IRFaci inferred from such relationships is biased towards low values. Also, it is increasingly evident that different cloud regimes show different sensitivities to aerosols (Stevens and Feingold, 2009). Averaging statistics over regimes thus bias the inferred IRFaci (Gryspeerdt et al., 2014b). AR5 concluded that IRFaci estimates tied to satellite studies generally show weak IRFaci (Boucher et al., 2013), but when correcting for the biases discussed above, this is no longer the case.

Since AR5, several studies assessed the global IRFaci from satellite observations using different methods (Table 7.7). All studies relied on statistical relationships between aerosol- and cloud quantities to infer sensitivities. Four studies inferred IRFaci by estimating the anthropogenic perturbation of N_d. For this, Bellouin et al. (2013a) and Rémy et al. (2018) made use of regional-seasonal regressions between satellite-derived N_d and AOD following Quaas et al. (2008), while Gryspeerdt et al. (2017) used AI instead of AOD in the regression to infer IRFaci. McCoy et al. (2017a) instead used the sulphate specific mass derived in the MERRA aerosol reanalysis that assimilated MODIS AOD (Rienecker et al., 2011). All approaches have in common the need to identify the anthropogenic perturbation of the aerosol to assess IRFaci. Gryspeerdt et al. (2017) and Rémy et al. (2018) used the same approach as Bellouin et al. (2013a), while McCoy et al. (2017a) used an anthropogenic fraction from the AEROCOM multi-model ensemble (Schulz et al., 2006). Chen et al. (2014), Christensen et al. (2016b) and Christensen et al. (2017) derived the combination of IRFaci and the LWP adjustment to IRFaci ("intrinsic forcing" in their terminology). They relate AI and cloud albedo statistically and use the anthropogenic aerosol fraction from Bellouin et al. (2013a). This was further refined by Hasekamp et al. (2019) who used additional polarimetric satellite information over ocean to obtain a better proxy for CCN. They derived an IRFaci of –1.14 [–1.72 to –0.84] W m^{-2}. The variant by Christensen et al. (2017) is an update compared to the Chen et al. (2014) and Christensen et al. (2016b) studies in that it better accounts for ancillary influences on the aerosol retrievals such as aerosol swelling and 3D radiative effects. McCoy et al. (2020) used the satellite-observed hemispheric difference in N_d as an emergent constraint on IRFaci as simulated by GCMs to obtain a range of –1.2 to –0.6 W m^{-2} (95% confidence interval). Diamond et al. (2020) analysed the difference in clouds affected by ship emissions with unperturbed clouds and based on this inferred a global IRFaci of –0.69 [–0.99 to –0.44] W m^{-2}.

Summarising the above findings related to statistical relationships and causal aerosol effects on cloud properties, there is *high confidence* that anthropogenic aerosols lead to an increase in cloud droplet concentrations. Taking the average across the studies providing IRFaci estimates discussed above and considering the general agreement among estimates (Table 7.7), IRFaci is assessed to be –0.7 ± 0.5 W m^{-2} (*medium confidence*).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Multiple studies have found a positive relationship between cloud fraction and/or cloud LWP and aerosols (e.g., Nakajima et al., 2001; Kaufman and Koren, 2006; Quaas et al., 2009). Since AR5, however, it has been documented that factors independent of causal aerosol-cloud interactions heavily influence such statistical relationships. These include the swelling of aerosols in the high relative humidity in the vicinity of clouds (Grandey et al., 2013) and the contamination of aerosol retrievals next to clouds by cloud remnants and cloud-side scattering (Várnai and Marshak, 2015; Christensen et al., 2017). Stratifying relationships by possible influencing factors such as relative humidity (Koren et al., 2010) does not yield satisfying results since observations of the relevant quantities are not available at the resolution and quality required. Another approach to tackle this problem was to assess the relationship of cloud fraction with droplet concentration (Gryspeerdt et al., 2016; Michibata et al., 2016; Sato et al., 2018). The relationship between satellite-retrieved cloud fraction and N_d was found to be positive (Christensen et al., 2016b, 2017; Gryspeerdt et al., 2016), implying an overall adjustment that leads to a more negative ERFaci. However, since retrieved N_d is biased low for broken clouds this result has been called into question (Grosvenor et al., 2018). Zhu et al. (2018) proposed to circumvent this problem by considering N_d of only continuous thick cloud covers, on the basis of which Rosenfeld et al. (2019) still obtained a positive cloud fraction – N_d relationship.

The relationship between LWP and cloud droplet number is debated. Most recent studies (primarily based on MODIS data) find negative statistical relationships (Michibata et al., 2016; Toll et al., 2017; Sato et al., 2018; Gryspeerdt et al., 2019), while Rosenfeld et al. (2019) obtained a modest positive relationship. To increase confidence that observed relationships between aerosol emissions and cloud adjustments are causal, known emissions of aerosols and aerosol precursor gases into otherwise pristine conditions have been exploited. Ship exhaust is one such source. Goren and Rosenfeld (2014) suggested that both LWP and Cf increase in response to ship emissions, contributing approximately 75% to the total ERF_{aci} in mid-latitude stratocumulus. Christensen and Stephens (2011) found that such strong adjustments occur for open-cell stratocumulus regimes, while adjustments are comparatively small in closed-cell regimes. Volcanic emissions have been identified as another important source of information (Gassó, 2008). From satellite observations, Yuan et al. (2011) documented substantially larger Cf, higher cloud tops, reduced precipitation likelihood, and increased albedo in cumulus clouds in the plume of the Kilauea volcano. Ebmeier et al. (2014) confirmed the increased LWP and albedo for other volcanoes. In contrast, for the large Holuhraun eruption, Malavelle et al. (2017) did not find any large-scale change in LWP in satellite observations. However, when accounting for meteorological conditions, McCoy et al. (2018) concluded that for cyclonic conditions, the extra Holuhraun aerosol did enhance LWP. Toll et al. (2017) examined a large sample of volcanoes and found a distinct albedo effect, but only modest LWP changes on average. Gryspeerdt et al. (2019) demonstrated that the negative LWP – Nd relationship becomes very small when conditioned on a volcanic eruption, and therefore concluded that LWP adjustments are small in most regions. Similarly, Toll et al. (2019) studied clouds downwind of various anthropogenic aerosol sources using satellite observations and inferred an IRFaci of –0.52 W m^{-2} that was partly offset by 29% due to aerosol-induced LWP decreases.

Apart from adjustments involving LWP and Cf, several studies have also documented a negative relationship between cloud-top temperature and AOD/AI in satellite observations (e.g., Koren et al., 2005). Wilcox et al. (2016) proposed that this could be explained by BC absorption reducing boundary layer turbulence, which in turn could lead to taller clouds. However, it has been demonstrated that the satellite-derived relationships are affected by spurious co-variation (Gryspeerdt et al., 2014a), and it therefore remains unclear whether a systematic causal effect exists.

Identifying relationships between INP concentrations and cloud properties from satellites is intractable because the INPs generally represent a very small subset of the overall aerosol population at any given time or location. For ice clouds, only few satellite studies have investigated responses to aerosol perturbations so far. Gryspeerdt et al. (2018) find a positive relationship between aerosol and ice crystal number for cold cirrus under strong dynamical forcing, which could be explained by an overall larger number of solution droplets available for homogeneous freezing in polluted regions. Zhao et al. (2018) conclude that the sign of the ice crystal size – aerosol relationship depends on humidity. While these studies support modelling results finding that ice clouds do respond to anthropogenic aerosols (Section 7.3.3.2.2), no quantitative conclusions about IRFaci or ERFaci for ice clouds can be drawn based on satellite observations.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Only a handful of studies have estimated the LWP and Cf adjustments that are needed for satellite-based estimates of ERFaci. Chen et al. (2014) and Christensen et al. (2017) used the relationship between cloud fraction and AI to infer the cloud fraction adjustment. Gryspeerdt et al. (2017) used a similar approach but tried to account for non-causal aerosol – cloud fraction correlations by using N_d as a mediating factor. These three studies together suggest a global Cf adjustment that augments ERFaci relative to IRFaci by –0.5 ± 0.4 W m^{-2} (*medium confidence*). For global estimates of the LWP adjustment, evidence is even scarcer. Gryspeerdt et al. (2019) derived an estimate of the LWP adjustment using a method similar to Gryspeerdt et al. (2016). They estimated that the LWP adjustment offsets 0 to 60% of the (negative) IRFaci (0 to +0.3 W m^{-2}). Supporting an offsetting LWP adjustment, Toll et al. (2019) estimated a moderate LWP adjustment of 29% (+0.15 W m^{-2}). The adjustment due to LWP is assessed to be small, with a central estimate and *very likely* range of 0.2 ± 0.2 W m^{-2} , but with *low confidence* due to the limited number of studies available.

Combining IRFaci and the associated adjustments in Cf and LWP (adding uncertainties in quadrature), considering only liquid-water clouds and evidence from satellite observations alone, the central estimate and *very likely* range for ERFaci is assessed to be –1.0 ± 0.7 W m^{-2} (*medium confidence*). The confidence level and wider range for ERFaci compared to IRFaci reflect the relatively large uncertainties that remain in the adjustment contribution to ERFaci.

7.3.3.2.2 Model-based evidence

As in AR5, the representation of aerosol-cloud interactions in ESMs remains a challenge, due to the limited representation of important sub-gridscale processes, from the emissions of aerosols and their precursors to precipitation formation. ESMs that simulate ERFaci typically include aerosol-cloud interactions in liquid stratiform clouds only, while very few include aerosol interactions with mixed-phase-, convective-, and ice clouds. Adding to the spread in model-derived estimates of ERFaci is the fact that model configurations and assumptions vary across studies, for example when it comes to the treatment of oxidants, which influence aerosol formation, and their changes through time (Karset et al., 2018).

In AR5, ERFaci was assessed as the residual of the total aerosol ERF and ERFari, as the total aerosol ERF was easier to calculate based on available model simulations (Boucher et al., 2013). The central estimates of total aerosol ERF and ERFari in AR5 were –0.9 W m^{-2} and –0.45 W m^{-2}, respectively, yielding an ERFaci estimate of –0.45 W m^{-2}. This value is much less negative than the bottom-up estimate of ERFaci from ESMs presented in AR5 (–1.4 W m^{-2}) and efforts have been made since to reconcile this difference. Zelinka et al. (2014) estimated ERFaci to be –0.96 ± 0.55 W m^{-2} (including semi-direct effects, and with land-surface cooling effect applied) based on nine CMIP5 models (Table 7.6). The corresponding ERFaci estimate based on 17 RFMIP models from CMIP6 is slightly less negative at –0.86 ± 0.57 W m^{-2} (Table 7.6). Other post-AR5 estimates of ERFaci based on single model studies are either in agreement with or slightly larger in magnitude than the CMIP6 estimate (Gordon et al., 2016; Fiedler et al., 2017; Neubauer et al., 2017; Karset et al., 2018; Regayre et al., 2018; Zhou et al., 2018b; Fiedler et al., 2019; Golaz et al., 2019a; Diamond et al., 2020).

The adjustment contribution to the CMIP6 ensemble mean ERFaci is –0.20 W m^{-2}, though with considerable differences between the models (Smith et al., 2020a). Generally, this adjustment in ESMs arises mainly from LWP changes (e.g., Ghan et al., 2016), while satellite observations suggest that cloud cover adjustments dominate and that aerosol effects on LWP are over-estimated in ESMs (Bender et al., 2019). Large-eddy-simulations also tend to suggest an over-estimated aerosol effect on cloud lifetime in ESMs, but some report an aerosol-induced decrease in cloud cover that is at odds with satellite observations (Seifert et al., 2015). Despite this potential disagreement when it comes to the dominant adjustment mechanism, a substantial negative contribution to ERFaci from adjustments is supported both by observational and modelling studies.

Contributions to ERFaci from anthropogenic aerosols acting as INPs are generally not included in CMIP6 models. Two global modelling studies incorporating parameterizations based on recent laboratory studies both found a negative contribution to ERFaci (Penner et al., 2018; McGraw et al., 2020), with central estimates of –0.3 and –0.13 W m^{-2}, respectively. However, previous studies have produced model estimates

ACCEPTED VERSION SUBJECT TO FINAL EDITING

of opposing signs (Storelvmo, 2017). There is thus *limited evidence* and *medium agreement* for a small negative contribution to ERFaci from anthropogenic INP-induced cirrus modifications (*low confidence*).

Similarly, aerosol effects on deep convective clouds are typically not incorporated in ESMs. However, cloud-resolving modelling studies support non-negligible aerosol effects on the radiative properties of convective clouds and associated detrained cloud anvils (Tao et al., 2012). While global ERF estimates are currently not available for these effects, the fact that they are missing in most ESMs adds to the uncertainty range for the model-based ERFaci.

From model-based evidence, ERFaci is assessed to $–1.0 \pm 0.8$ W m^{-2} (*medium confidence*). This assessment uses the mean ERFaci in Table 7.6 as a starting point, but further allows for a small negative ERF contribution from cirrus clouds. The uncertainty range is based on those reported in Table 7.6, but widened to account for uncertain but *likely* non-negligible processes currently unaccounted for in ESMs.

7.3.3.2.3 Overall assessment of ERFaci

The assessment of ERFaci based on observational evidence alone ($–1.0 \pm 0.7$ W m^{-2}) is very similar to the one based on model-evidence alone ($–1.0 \pm 0.8$ W m^{-2}), in strong contrast to what was reported in AR5. This reconciliation of observation-based and model-based estimates is the result of considerable scientific progress and reflects comparable revisions of both model-based and observation-based estimates. The strong agreement between the two largely independent lines of evidence increases confidence in the overall assessment of the central estimate and *very likely* range for ERFaci of $–1.0 \pm 0.7$ W m^{-2} (*medium confidence*). The assessed range is consistent with but narrower than that reported by the review of Bellouin et al. (2019) of –2.65 to –0.07 W m^{-2}. The difference is primarily due to a wider range in the adjustment contribution to ERFaci in Bellouin et al. (2019), however adjustments reported relative to IRFaci ranging from 40% to 150% in that study are fully consistent with the ERFaci assessment presented here.

7.3.3.3 Energy budget constraints on the total aerosol ERF

Energy balance models of reduced complexity have in recent years increasingly been combined with Monte Carlo approaches to provide valuable "top-down" (also called inverse) observational constraints on the total aerosol ERF. These top-down approaches report ranges of aerosol ERF that are found to be consistent with the global mean temperature record and, in some cases, also observed ocean heat uptake. However, the total aerosol ERF is also used together with the historical temperature record in Section 7.5 to constrain ECS and TCR. Using top-down estimates as a separate line of evidence also for the total aerosol ERF would therefore be circular. Nevertheless, it is useful to examine the development of these estimates since AR5 and the degree to which these estimates are consistent with the upper and lower bounds of the assessments of total aerosol ERF (ERFari+ERFaci).

When the first top-down estimates emerged (e.g., Knutti et al., 2002), it became clear that some of the early ("bottom-up") ESM estimates of total aerosol ERF were inconsistent with the plausible top-down range. However, as more inverse estimates have been published, it has increasingly become clear that they too are model-dependent and span a wide range of ERF estimates, with confidence intervals that in some cases do not overlap (Forest, 2018). It has also become evident that these methods are sensitive to revised estimates of other forcings and/or updates to observational data sets. A recent review of 19 such estimates reported a mean of –0.77 W m^{-2} for the total aerosol ERF, and a 95% confidence interval of –1.15 W m^{-2} to –0.31 W m^{-2} (Forest, 2018). Adding to that review, a more recent study using the same approach reported an estimate of total aerosol ERF of –0.89 [–1.82 to –0.01] W m^{-2} (Skeie et al., 2018). However, in the same study, an alternative way of incorporating ocean heat content in the analysis produced a total aerosol ERF estimate of –1.34 [–2.20 to –0.46] W m^{-2}, illustrating the sensitivity to the manner in which observations are included. A new approach to inverse estimates took advantage of independent climate radiative response estimates from eight prescribed SST and sea-ice concentration simulations over the historical period to estimate the total anthropogenic ERF. From this a total aerosol ERF of –0.8 [–1.6 to +0.1] W m^{-2} was derived (valid for near-present relative to the late 1800s). This range was found to be more invariant to

ACCEPTED VERSION SUBJECT TO FINAL EDITING

parameter choices than earlier inverse approaches (Andrews and Forster, 2020).

Beyond the inverse estimates described above, other efforts have been made since AR5 to constrain the total aerosol ERF. For example, Stevens (2015) used a simple (1-dimensional) model to simulate the historical total aerosol ERF evolution consistent with the observed temperature record. Given the lack of temporally extensive cooling trends in the 20th century record and the fact that the historical evolution of greenhouse gas forcing is relatively well constrained, the study concluded that a more negative total aerosol ERF than –1.0 W m^{-2} was incompatible with the historical temperature record. This was countered by Kretzschmar et al. (2017), who argued that the model employed in Stevens (2015) was too simplistic to account for the effect of geographical redistributions of aerosol emissions over time. Following the logic of Stevens (2015), but basing their estimates on a subset of CMIP5 models as opposed to a simplified modelling framework, they argued that a total aerosol ERF as negative as –1.6 W m^{-2} was consistent with the observed temperature record. Similar arguments were put forward by Booth et al. (2018), who emphasized that the degree of non-linearity of the total aerosol ERF with aerosol emission is a central assumption in Stevens (2015).

The historical temperature record was also the key observational constraint applied in two additional studies (Rotstayn et al., 2015; Shindell et al., 2015) based on a subset of CMIP5 models. Rotstayn et al. (2015) found a strong temporal correlation (> 0.9) between the total aerosol ERF and the global surface temperature. They used this relationship to produce a best estimate for the total aerosol ERF of –0.97 W m^{-2}, but with considerable unquantified uncertainty, in part due to uncertainties in the TCR. Shindell et al. (2015) came to a similar best estimate for the total aerosol ERF of –1.0 W m^{-2} and a 95% confidence interval of –1.4 to –0.6 W m^{-2} but based this on spatial temperature and ERF patterns in the models in comparison with observed spatial temperature patterns.

A separate observational constraint on the total ERF was proposed by Cherian et al. (2014), who compared trends in downward fluxes of solar radiation observed at surface stations across Europe (described in Section 7.2.2.3) to those simulated by a subset of CMIP5 models. Based on the relationship between solar radiation trends and the total aerosol ERF in the models, they inferred a total aerosol ERF of –1.3 W m^{-2} and a standard deviation of ± 0.4 W m^{-2}.

Based solely on energy balance considerations or other observational constraints, it is *extremely likely* that the total aerosol ERF is negative (*high confidence*), but *extremely unlikely* that the total aerosol ERF is more negative than –2.0 W m^{-2} (*high confidence*).

7.3.3.4 Overall assessment of total aerosol ERF

In AR5 (Boucher et al., 2013), the overall assessment of total aerosol ERF (ERFari+aci) used the median of all ESM estimates published prior to AR5 of –1.5 [–2.4 to –0.6] W m^{-2} as a starting point, but placed more confidence in a subset of models that were deemed more complete in their representation of aerosol-cloud interactions. These models, which included aerosol effects on mixed-phase, ice and/or convective clouds, produced a smaller estimate of –1.38 W m^{-2}. Likewise, studies that constrained models with satellite observations (five in total), which produced a median estimate of –0.85 W m^{-2}, were given extra weight. Furthermore, a longwave ERFaci of 0.2 W m^{-2} was added to studies that only reported shortwave ERFaci values. Finally, based on higher resolution models, doubt was raised regarding the ability of ESMs to represent the cloud adjustment component of ERFaci with fidelity. The expert judgement was therefore that aerosol effects on cloud lifetime were too strong in the ESMs, further reducing the overall ERF estimate. The above lines of argument resulted in a total aerosol assessment of –0.9 [–1.9 to –0.1] W m^{-2} in AR5.

Here, the best estimate and range is revised relative to AR5 (Boucher et al., 2013), partly based on updates to the above lines of argument. Firstly, the studies that included aerosol effects on mixed-phase clouds in AR5 relied on the assumption that anthropogenic black carbon (BC) could act as INPs in these clouds, which has since been challenged by laboratory experiments (Kanji et al., 2017; Vergara-Temprado et al., 2018). There is no observational evidence of appreciable ERFs associated with aerosol effects on mixed-phase and ice clouds (Section 7.3.3.2.1), and modelling studies disagree when it comes to both their magnitude and sign

ACCEPTED VERSION SUBJECT TO FINAL EDITING

(Section 7.3.3.2.2). Likewise, very few ESMs incorporate aerosol effects on deep convective clouds, and cloud-resolving modelling studies report different effects on cloud radiative properties depending on environmental conditions (Tao et al., 2012). Thus, it is not clear whether omitting such effects in ESMs would lead to any appreciable ERF biases, or if so, what the sign of such biases would be. As a result, all ESMs are given equal weight in this assessment. Furthermore, there is now a considerably expanded body of literature which suggests that early modelling studies that incorporated satellite observations may have resulted in overly conservative estimates of the magnitude of ERFaci (Section 7.3.3.2.1). Finally, based on an assessment of the longwave ERFaci in the CMIP5 models, the offset of +0.2 W m^{-2} applied in AR5 appears to be too large (Heyn et al., 2017). As in AR5, there is still reason to question the ability of ESMs to simulate adjustments in LWP and cloud cover in response to aerosol perturbation, but it is not clear that this will result in biases that exclusively increase the magnitude of the total aerosol ERF (Section 7.3.3.2.2).

The assessment of total aerosol ERF here uses the following lines of evidence: satellite-based evidence for IRFari, model-based evidence for IRFari and ERFari, satellite-based evidence of IRF/ERFaci, and finally model-based evidence for ERFaci. Based on this, ERFari and ERFaci for 2014 relative to 1750 are assessed to –0.3 ± 0.3 W m^{-2} and –1.0 ± 0.7 W m^{-2}, respectively. There is thus strong evidence for a substantive negative total aerosol ERF, which is supported by the broad agreement between observation-based and model-based lines of evidence for both ERFari and ERFaci that has emerged since AR5 (Gryspeerdt et al., 2020). However, considerable uncertainty remains, particularly with regards to the adjustment contribution to ERFaci, as well as missing processes in current ESMs, notably aerosol effects on mixed-phase, ice and convective clouds. This leads to a *medium confidence* in the estimate of ERFari+aci and a slight narrowing of the uncertainty range. Because the estimates informing the different lines of evidence are generally valid for approximately 2014 conditions, the total aerosol ERF assessment is considered valid for 2014 relative to 1750.

Combining the lines of evidence and adding uncertainties in quadrature, the ERFari+aci estimated for 2014 relative to 1750 is assessed to be –1.3 [–2.0 to –0.6] W m^{-2} *(medium confidence)*. The corresponding range from Bellouin et al. (2019) is –3.15 to –0.35 W m^{-2}, thus there is agreement for the upper bound while the lower bound assessed here is less negative. A lower bound more negative than -2.0 W m^{-2} is not supported by any of the assessed lines of evidence. There is *high confidence* that ERFaci contributes most (75–80%) to the total aerosol effect (ERFari+aci). In contrast to AR5 (Boucher et al., 2013), it is now *virtually certain* that the total aerosol ERF is negative. Figure 7.5 depicts the aerosol ERFs from the different lines of evidence along with the overall assessments.

As most modelling and observational estimates of aerosol ERF have end points in 2014 or earlier, there is limited evidence available for the assessment of how aerosol ERF has changed from 2014 to 2019. However, based on a general reduction in global mean AOD over this period (Chapter 2, Section 2.2.6, Figure 2.9), combined with a reduction in emissions of aerosols and their precursors in updated emission inventories (Hoesly et al., 2018), the aerosol ERF is assessed to have decreased in magnitude from about 2014 to 2019 *(medium confidence)*. Consistent with Chapter 2, Figure 2.10, the change in aerosol ERF from about 2014 to 2019 is assessed to be +0.2 W m^{-2}, but with *low confidence* due to limited evidence. Aerosols are therefore assessed to have contributed an ERF of –1.1 [–1.7 to –0.4] W m^{-2} over 1750–2019 (*medium confidence*).

[START FIGURE 7.5 HERE]

Figure 7.5: Net aerosol effective radiative forcing from different lines of evidence. The headline AR6 assessment of –1.3 [–2.0 to –0.6] W m^{-2} is highlighted in purple for 1750–2014 and compared to the AR5 assessment of –0.9 [–1.9 to –0.1] W m^{-2} for 1750–2011. The evidence comprising the AR6 assessment is shown below this: energy balance constraints (–2 to 0 W m^{-2} with no best estimate), observational evidence from satellite retrievals of –1.4 [–2.2 to –0.6] W m^{-2}, and climate model-based evidence of –1.25 [–2.1 to –0.4] W m^{-2}. Estimates from individual CMIP5 (Zelinka et al., 2014) and CMIP6 (Smith et al., 2020a and Table 7.6) models are depicted by blue and red crosses respectively. For each line of evidence the assessed best-estimate contributions from ERFari and ERFaci are shown with darker and paler shading respectively. The observational assessment for ERFari is taken from the IRFari. Uncertainty ranges are given in black bars for the total aerosol ERF and depict *very likely* ranges. Further details on data sources

ACCEPTED VERSION SUBJECT TO FINAL EDITING

and processing are available in the chapter data table (Table 7.SM.14).

[END FIGURE 7.5 HERE]

7.3.4 Other agents

In addition to the large anthropogenic ERFs associated with WMGHGs and atmospheric aerosols assessed in Sections 7.3.2 and 7.3.3, land use change, contrails and aviation-induced cirrus and light absorbing particles deposited on snow and ice have also contributed to the overall anthropogenic ERF and are assessed in Sections 7.3.4.1, 7.3.4.2 and 7.3.4.3. Changes in solar irradiance, galactic cosmic rays and volcanic eruptions since pre-industrial times combined represent the natural contribution to the total (anthropogenic + natural) ERF and are discussed in Sections 7.3.4.4, 7.3.4.5 and 7.3.4.6.

7.3.4.1 Land use

Land use forcing is defined as those changes in land surface properties directly caused by human activity rather than by climate processes (see also Chapter 2, Section 2.2.7). Land use change affects the surface albedo. For example, deforestation typically replaces darker forested areas with brighter cropland, and thus imposes a negative radiative forcing on climate, while afforestation and reforestation can have the opposite effect. Precise changes depend on the nature of the forest, crops and underlying soil. Land use change also affects the amount of water transpired by vegetation (Devaraju et al., 2015). Irrigation of land directly affects the evaporation (Sherwood et al., 2018) causing a global increase of 32 500 $m^3 s^{-1}$ due to human activity. Changes in evaporation and transpiration affect the latent heat budget, but do not directly affect the top-of-atmosphere radiative fluxes. The lifetime of water vapour is so short that the effect of changes in evaporation on the greenhouse contribution of water vapour are negligible (Sherwood et al., 2018). However, evaporation can affect the ERF through adjustments, particularly through changes in low cloud amounts. Land management affects the emissions or removal of greenhouse gases from the atmosphere (such as CO_2, CH_4, N_2O). These emission changes have the greatest effect on climate (Ward et al., 2014), however they are already included in greenhouse gas inventories. Land use change also affects the emissions of dust and biogenic volatile organic compounds (BVOCs), which form aerosols and affect the atmospheric concentrations of ozone and methane (Chapter 6, Section 6.2.2). The effects of land use on surface temperature and hydrology were recently assessed in SRCCL (Jia et al., 2019).

Using the definition of ERF from Section 7.1, the adjustment in land surface temperature is excluded from the definition of ERF, but changes in vegetation and snow cover (resulting from land use change) are included (Boisier et al., 2013). Land use change in the mid-latitudes induces a substantial amplifying adjustment in snow cover. Few climate model studies have attempted to quantify the ERF of land use change. Andrews et al. (2017b) calculated a very large surface albedo ERF (–0.47 W m^{-2}) from 1860 to 2005 in the HadGEM2-ES model although they did not separate out the surface albedo change from snow cover change. HadGEM2-ES is known to overestimate the amount of boreal trees and shrubs in the unperturbed state (Collins et al., 2011) so will tend to overestimate the ERF associated with land use change. The increases in dust in HadGEM2-ES contributed an extra –0.25 W m^{-2}, whereas cloud cover changes added a small positive adjustment (0.15 W m^{-2}) consistent with a reduction in transpiration. A multi-model quantification of land use forcing in CMIP6 models (excluding one outlier) (Smith et al., 2020a) found an IRF of –0.15 ± 0.12 W m^{-2} (1850 to 2014), and an ERF (correcting for land surface temperature change) of -0.11 ± 0.09 W m^{-2}. This shows a small positive adjustment term (mainly from a reduction in cloud cover. CMIP5 models show an IRF of –0.11 [–0.16 to –0.04] W m^{-2} (1850 to 2000) after excluding unrealistic models (Lejeune et al., 2020).

The contribution of land use change to albedo changes has recently been investigated using MODIS and AVHRR to attribute surface albedo to geographically-specific land cover types (Ghimire et al., 2014). When combined with a historical land use map (Hurtt et al., 2011) this gives a 1700 to 2005 SARF of –0.15 ± 0.01 W m^{-2} (of which –0.12 W m^{-2} is from 1850). This study accounted for correlations between

ACCEPTED VERSION SUBJECT TO FINAL EDITING

vegetation type and snow cover, but not the adjustment in snow cover identified in (Andrews et al., 2017b).

The indirect contributions of land use change through biogenic emissions is very uncertain. Decreases in biogenic volatile organic compounds (BVOCs) reduce ozone and methane (Unger, 2014), but also reduce the formation of organic aerosols and their effects of clouds Scott et al. (2017). Adjustments through changes in aerosols and chemistry are model dependent (Zhu et al., 2019a; Zhu and Penner, 2020), and it is not yet possible to make an assessment based on a limited number of studies.

The contribution of irrigation (mainly to low cloud amount) is assessed as –0.05 [–0.1 to 0.05] W m^{-2} for the historical period (Sherwood et al., 2018).

Since the CMIP5 and CMIP6 modelling studies are in agreement with Ghimire et al. (2014), that study is used as the assessed albedo ERF. Adding the irrigation effect to this gives an overall assessment of the ERF from land use change of –0.20 ± 0.10 W m^{-2} (*medium confidence*). Changes in ERF since 2014 are assumed to be small compared to the uncertainty, so this ERF applies to the period 1750 to 2019. The uncertainty range includes uncertainties in the adjustments.

7.3.4.2 Contrails and aviation-induced cirrus

ERF from contrails and aviation-induced cirrus is taken from the assessment of Lee et al. (2020), at 0.057 [0.019 to 0.098] W m^{-2} in 2018 (see Chapter 6, Section 6.6.2 for an assessment of the total effects of aviation). This is rounded up to address its *low confidence* and the extra year of air traffic to give an assessed ERF over 1750–2019 of 0.06 [0.02 to 0.10]. This assessment is given *low confidence* due to the potential for missing processes to affect the magnitude of contrails and aviation-induced cirrus ERF.

7.3.4.3 Light absorbing particles on snow and ice

In AR5, it was assessed that the effects of light absorbing particles (LAPs) did probably not significantly contribute to recent reductions in Arctic ice and snow (Vaughan et al., 2013). The SARF from LAPs on snow and ice was assessed to +0.04 [+0.02 to +0.09] W m^{-2} (Boucher et al., 2013), a range appreciably lower than the estimates given in AR4 (Forster et al., 2007). This effect was assessed to be *low confidence* (*medium evidence, low agreement*) (Table 8.5 in Myhre et al., 2013b).

Since AR5 there has been progress in the understanding of the physical state and processes in snow that governs the albedo reduction by black carbon (BC). The SROCC (IPCC, 2019a) assessed that there is *high confidence* that darkening of snow by deposition of BC and other light absorbing aerosol species increases the rate of snow melt (Section 2.2 in Hock et al., 2019; Section 3.4 in Meredith et al., 2019). He et al. (2018a) found that taking into account the non-spherical shape of snow grains and internal mixing of BC in snow both significantly altered the effects of BC on snow albedo. The reductions of snow albedo by dust and black carbon have been measured and characterised in the Arctic, the Tibetan Plateau, and mid latitude regions subject to seasonal snowfall including North America and Northern and Eastern Asia (Qian et al., 2015).

Since AR5, two further studies of global IRF from black carbon on snow deposition are available, with best estimates of 0.01 W m^{-2} and 0.04 W m^{-2} (Lin et al., 2014; Namazi et al., 2015). Organic carbon deposition on snow and ice has been estimated to contribute a small positive IRF of 0.001 to 0.003 W m^{-2} (Lin et al., 2014). No comprehensive global assessments of mineral dust deposition on snow are available, although the effects are potentially large in relation to the total LAPs on snow and ice forcing (Yasunari et al., 2015).

Most radiative forcing estimates have a regional emphasis. The regional focus makes estimating a global mean radiative forcing from aggregating different studies challenging, and the relative importance of each region is expected to change if the global pattern of emission sources changes (Bauer et al., 2013). The lower bound of the assessed range of black carbon on snow and ice is extended to zero to encompass Lin et al.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

(2014), with the best estimate unchanged resulting in 0.04 [0.00 to 0.09] W m^{-2}. The efficacy of black carbon on snow forcing was estimated to be 2 to 4 times as large as for an equivalent CO_2 forcing as the effects are concentrated at high latitudes in the cryosphere (Bond et al., 2013). However, it is unclear how much of this effect is due to radiative adjustments leading to a higher ERF, and how much comes from a less negative feedback α due the high latitude nature of the forcing. To estimate the overall ERF, the IRF is doubled assuming that part of the increased efficacy is due to adjustments. This gives an overall assessed ERF of +0.08 [0.00 to 0.18] W m^{-2}, with *low confidence*.

7.3.4.4 Solar

Variations in the total solar irradiance (TSI) represent a natural external forcing agent. The dominant cycle is the solar 11-year activity cycle, which is superimposed on longer cycles (Chapter 2, Section 2.2). Over the last three 11-year cycles, the peak-to-trough amplitude in TSI has differed by about 1 W m^{-2} between solar maxima and minima (Chapter 2, Figure 2.2).

The fractional variability in the solar irradiance, over the solar cycle and between solar cycles, is much greater at short wavelengths in the 200–400 nm band than for the broad visible/IR band that dominates TSI (Krivova et al., 2006). The IRF can be derived simply by ΔTSI × (1 – albedo)/4 irrespective of wavelength, where the best estimate of the planetary albedo is usually taken to be 0.29 and ΔTSI represents the change in total solar irradiance (Stephens et al., 2015). (The factor 4 arises because TSI is per unit area of Earth cross section presented to the Sun and IRF is per unit area of Earth's surface). The adjustments are expected to be wavelength dependent. Gray et al. (2009) determined a stratospheric temperature adjustment of –22% to spectrally resolved changes in the solar radiance over one solar cycle. This negative adjustment is due to stratospheric heating from increased absorption by ozone at the short wavelengths, increasing the outgoing longwave radiation to space. A multi-model comparison (Smith et al., 2018b) calculated adjustments of –4% due to stratospheric temperatures and –6% due to tropospheric processes (mostly clouds), for a change in TSI across the spectrum (Figure 7.4). The smaller magnitude of the stratospheric temperature adjustment is consistent with the broad spectral change rather than the shorter wavelengths characteristic of solar variation. A single model study also found an adjustment that acts to reduce the forcing (Modak et al., 2016). While there has not yet been a calculation based on the appropriate spectral change, the –6% tropospheric adjustment from Smith et al. (2018b) is adopted along with the Gray et al. (2009) stratospheric temperature adjustment. The ERF due to solar variability over the historical period is therefore represented by 0.72 × ΔTSI × (1 – albedo)/4 using the TSI timeseries from Chapter 2, Section 2.2.1.

AR5 (Myhre et al., 2013b) assessed solar SARF from around 1750 to 2011 to be 0.05 [0.00 to 0.10] W m^{-2} which was computed from the seven-year mean around the solar minima in 1745 (being closest to 1750) and 2008 (being the most recent solar minimum). The inclusion of tropospheric adjustments that reduce ERF (compared to SARF in AR5) has a negligible effect on the overall forcing. Prior to the satellite era, proxy records are used to reconstruct historical solar activity. In AR5, historical records were constructed using observations of solar magnetic features. In this assessment historical time series are constructed from radiogenic compounds in the biosphere and in ice cores that are formed from cosmic rays (Steinhilber et al., 2012).

In this assessment the TSI from the Paleoclimate Model Intercomparison Project Phase 4 (PMIP4) reconstruction is used (Jungclaus et al., 2017; Chapter 2, Section 2.2.1). Proxies constructed from the ^{14}C and ^{10}Be radiogenic records for the SATIRE-M model (Vieira et al., 2011) and ^{14}C record for the PMOD model (Shapiro et al., 2011) for the 1745 solar minimum provide 1745 to 2008 ERFs of –0.01, –0.02 and 0.00 W m^{-2} respectively. An independent dataset from the National Oceanic and Atmospheric Administration's Climate Data Record (Coddington et al., 2016; Lean, 2018) provides a 1745 to 2008 ERF of +0.03 W m^{-2}. One substantially higher ERF estimate of +0.35 W m^{-2} derived from TSI reconstructions is provided by Egorova et al. (2018). However, the estimate from Egorova et al. (2018) hinges on assumptions about long-term changes in the quiet Sun for which there is no observed evidence. Lockwood and Ball (2020) analysed the relationship of observed changes in cosmic ray fluxes and recent, more accurate, TSI data and derived ERF between –0.01 and +0.02 W m^{-2} and Yeo et al. (2020) modelling showed the

ACCEPTED VERSION SUBJECT TO FINAL EDITING

maximum possible ERF to be 0.26 ± 0.09 W m^{-2}. Hence the Egorova et al. (2018) estimate is not explicitly taken into account in the assessment presented in this section.

In contrast to AR5, the solar ERF in this assessment uses full solar cycles rather than solar minima. The pre-industrial TSI is defined as the mean from all complete solar cycles from the start of the ^{14}C SATIRE-M proxy record in 6755 BCE to 1744 CE. The mean TSI from solar cycle 24 (2009–2019) is adopted as the assessment period for 2019. The best estimate solar ERF is assessed to be 0.01 W m^{-2}, using the ^{14}C reconstruction from SATIRE-M, with a *likely* range of –0.06 to +0.08 W m^{-2} (*medium confidence*). The uncertainty range is adopted from the evaluation of Lockwood and Ball (2020) using a Monte Carlo analysis of solar activity from the Maunder Minimum to 2019 from several datasets, leading to an ERF of –0.12 to +0.15 W m^{-2}. The Lockwood and Ball (2020) full uncertainty range is halved as the period of reduced solar activity in the Maunder Minimum had ended by 1750 *(medium confidence)*.

7.3.4.5 Galactic Cosmic Rays

Variations in the flux of galactic cosmic rays (GCR) reaching the atmosphere are modulated by solar activity and affect new particle formation in the atmosphere through their link to ionization of the troposphere (Lee et al., 2019). It has been suggested that periods of high GCR flux correlate with increased aerosol and CCN concentrations and therefore also with cloud properties (e.g., Dickinson, 1975; Kirkby, 2007).

Since AR5, the link between GCR and new particle formation has been more thoroughly studied, particularly by experiments in the CERN CLOUD chamber (Cosmics Leaving OUtdoor Droplets) (Dunne et al., 2016; Kirkby et al., 2016; Pierce, 2017). By linking the GCR-induced new particle formation from CLOUD experiments to CCN, Gordon et al. (2017) found the CCN concentration for low clouds to differ by 0.2% to 0.3% between solar maximum and solar minimum of the solar cycle. Combined with relatively small variations in the atmospheric ion concentration over centennial time scales (Usoskin et al., 2015), it is therefore unlikely that cosmic ray intensity affects present day climate via nucleation (Yu and Luo, 2014; Dunne et al., 2016; Pierce, 2017; Lee et al., 2019).

Studies continue to seek a relationship between GCR and properties of the climate system based on correlations and theory. Svensmark et al. (2017) proposed a new mechanism for ion-induced increase in aerosol growth rate and subsequent influence on the CCN concentration. The study does not include an estimate of the resulting effect on atmospheric CCN concentration and cloud radiative properties. Furthermore, Svensmark et al. (2009, 2016) find correlations between GCRs and aerosol and cloud properties in satellite and ground based data. Multiple studies investigating this link have challenged such correlations (Kristjánsson et al., 2008; Calogovic et al., 2010; Laken, 2016).

AR5 concluded that the GCR effect on CCN is too weak to have any detectable effect on climate and no robust association was found between GCR and cloudiness (Boucher et al., 2013). Published literature since then robustly support these conclusions with key laboratory, theoretical and observational evidence. There is *high confidence* that GCRs contribute a negligible ERF over the period 1750 to 2019.

7.3.4.6 Volcanic aerosols

There is large episodic negative radiative forcing associated with SO_2 being ejected into the stratosphere from explosive volcanic eruptions, accompanied by more frequent smaller eruptions (Chapter 2, Figure 2.2; Cross-Chapter Box 4.1). From SO_2 gas, reflective sulphate aerosol is formed in the stratosphere where it may persist for months, reducing the incoming solar radiation. The volcanic SARF in AR5 (Myhre et al., 2013b) was derived by scaling the stratospheric aerosol optical depth (SAOD) by a factor of –25 W m^{-2} per unit SAOD from Hansen et al. (2005b). Quantification of the adjustments to SAOD perturbations from climate model simulations have determined a significant positive adjustment driven by a reduction in cloud amount (Marshall et al., 2020; Figure 7.4). Analysis of CMIP5 models provide a mean ERF of –20 W m^{-2} per unit SAOD (Larson and Portmann, 2016). Single model studies with successive generations of Hadley Centre

ACCEPTED VERSION SUBJECT TO FINAL EDITING

climate models produce estimates between –17 and –19 W m^{-2} per unit SAOD (Gregory et al., 2016; Marshall et al., 2020), with some evidence that ERF may be non-linear with SAOD for large eruptions (Marshall et al., 2020). Analysis of the volcanically active periods of 1982-1985 and 1990-1994 using the CESM1(WACCM) aerosol-climate model provided an SAOD to ERF relationship of –21.5 (± 1.1) W m^{-2} per unit SAOD (Schmidt et al., 2018). Volcanic SO_2 emissions may contribute a positive forcing through effects on upper tropospheric ice clouds, due to additional ice nucleation on volcanic sulphate particles (Friberg et al., 2015; Schmidt et al., 2018), although one observational study found no significant effect (Meyer et al., 2015). Due to *limited agreement*, the contribution to volcanic ERF due to sulphate aerosol effects on ice clouds is not included in the overall assessment.

Non-explosive volcanic eruptions generally yield negligible global ERFs due to the short atmospheric lifetimes (a few weeks) of volcanic aerosols in the troposphere. However, as discussed in Section 7.3.3.2, the massive fissure eruption in Holuhraun, Iceland persisted for months in 2014 and 2015 and did in fact result in a marked and persistent reduction in cloud droplet radii and a corresponding increase in cloud albedo regionally (Malavelle et al., 2017). This shows that non-explosive fissure eruptions can lead to strong regional and even global ERFs, but because the Holuhraun eruption occurred in NH winter, solar insolation was weak and the observed albedo changes therefore did not result in an appreciable global ERF (Gettelman et al., 2015).

The ERF for volcanic stratospheric aerosols is assessed to be –20 ± 5 W m^{-2} per unit SAOD (*medium confidence*) based on the CMIP5 multi-model mean from the Larson and Portmann (2016) SAOD forcing efficiency calculations combined with the single-model results of Gregory et al. (2016), Schmidt et al. (2018) and Marshall et al. (2020). This is applied to the SAOD timeseries from Chapter 2, Section 2.2.2 to generate a timeseries of ERF and temperature response shown in Chapter 2, Figure 2.2 and Figure 7.8 respectively. The period from 500 BC to 1749, spanning back to the start of the record of Toohey and Sigl (2017), is defined as the pre-industrial baseline and the volcanic ERF is calculated using an SAOD anomaly from this long-term mean. As in AR5, a pre-industrial to present-day ERF assessment is not provided due to the episodic nature of volcanic eruptions.

7.3.5 Synthesis of Global Mean Radiative Forcing, Past and Future

7.3.5.1 Major changes in forcing since IPCC AR5

AR5 introduced the concept of ERF and radiative adjustments, and made a preliminary assessment that the tropospheric adjustments were zero for all species other than the effects of aerosol-cloud interaction and black carbon. Since AR5, new studies have allowed for a tentative assessment of values for tropospheric adjustments to CO_2, CH_4, N_2O, some CFCs, solar forcing, and stratospheric aerosols, and to place a tighter constraint on adjustments from aerosol-cloud interaction (Sections 7.3.2, 7.3.3, 7.3.4). In AR6, the definition of ERF explicitly removes the land-surface temperature change as part of the forcing, in contrast to AR5 where only sea-surface temperatures were fixed. The ERF is assessed to be a better predictor of modelled equilibrium temperature change (i.e. less variation in feedback parameter) than SARF (Section 7.3.1).

As discussed in Section 7.3.2, the radiative efficiencies for CO_2, CH_4 and N_2O have been updated since AR5 (Etminan et al., 2016). There has been a small (1%) increase in the stratospheric-temperature adjusted CO_2 radiative efficiency, and a +5% tropospheric adjustment has been added. The stratospheric-temperature adjusted radiative efficiency for CH_4 is increased by 25% (*high confidence*). The tropospheric adjustment is tentatively assessed to be –14% *(low confidence*). A +7% tropospheric adjustment has been added to the radiative efficiency for N_2O and +12% to CFC-11 and CFC-12 (*low confidence*).

For aerosols there has been a convergence of model and observational estimates of aerosol forcing, and the partitioning of the total aerosol ERF has changed. Compared to AR5 a greater fraction of the ERF is assessed to come from ERFaci compared to the ERFari. It is now assessed as *virtually certain* that the total aerosol ERF (ERFari+aci) is negative.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

7.3.5.2 Summary ERF assessment

Figure 7.6 shows the industrial-era ERF estimates for 1750 to 2019 for the concentration change in different forcing agents. The assessed uncertainty distributions for each individual component are combined with a 100,000-member Monte Carlo simulation that samples the different distributions, assuming they are independent, to obtain the overall assessment of total present-day ERF (Supplementary Material 7.SM.1). The corresponding emissions based ERF figure is shown in Chapter 6, Figure 6.12.

[START FIGURE 7.6 HERE]

Figure 7.6: Change in effective radiative forcing from 1750 to 2019 by contributing forcing agents (carbon dioxide, other well-mixed greenhouse gases (WMGHGs), ozone, stratospheric water vapour, surface albedo, contrails and aviation-induced cirrus, aerosols, anthropogenic total, and solar). Solid bars represent best estimates, and *very likely* (5–95%) ranges are given by error bars. Non-CO_2 WMGHGs are further broken down into contributions from methane (CH_4), nitrous oxide (N_2O) and halogenated compounds. Surface albedo is broken down into land use changes and light absorbing particles on snow and ice. Aerosols are broken down into contributions from aerosol-cloud interactions (ERFaci) and aerosol-radiation interactions (ERFari). For aerosols and solar, the 2019 single-year values are given (Table 7.8) that differ from the headline assessments in both cases. Volcanic forcing is not shown due to the episodic nature of volcanic eruptions. Further details on data sources and processing are available in the chapter data table (Table 7.SM.14).

[END FIGURE 7.6 HERE]

[START TABLE 7.8 HERE]

Table 7.8: Summary table of ERF estimates for AR6 and comparison with the four previous IPCC assessment reports. Prior to AR5 values are SARF. For AR5 ari and aci are ERF, all other values assume ERF equals SARF. 5% to 95% ranges are shown. Volcanic ERF is not added to the table due to the episodic nature of volcanic eruptions which makes it difficult to compare to the other forcing mechanisms. Solar ERF is based on TSI and not spectral variation.

[END TABLE 7.8 HERE]

The total anthropogenic ERF over the industrial era (1750–2019) is estimated as 2.72 [1.96 to 3.48] W m^{-2} (Table 7.8; Annex III) (*high confidence)*. This represents a 0.43 W m^{-2} increase over the assessment made in AR5 (Myhre et al., 2013b) for the period 1750–2011. This increase is a result of compensating effects. Atmospheric concentration increases of greenhouse gases since 2011 and upwards revisions of their forcing estimates have led to a 0.59 W m^{-2} increase in their ERF. Whereas, the total aerosol ERF is assessed to be more negative compared to AR5, due to revised estimates rather than trends *(high confidence)*.

Greenhouse gases, including ozone and stratospheric water vapour from methane oxidation, are estimated to

ACCEPTED VERSION SUBJECT TO FINAL EDITING

contribute an ERF of 3.84 [3.46 to 4.22] W m^{-2} over 1750–2019. Carbon dioxide continues to contribute the largest part (56 ± 16 %) of this GHG ERF (*high confidence*).

As discussed in Section 7.3.3, aerosols have in total contributed an ERF of –1.1 [–1.7 to –0.4] W m^{-2} over 1750-2019 (*medium confidence*). Aerosol-cloud interactions contribute approximately 75–80% to this ERF with the remainder due to aerosol-radiation interactions (Table 7.8).

For the purpose of comparing forcing changes with historical temperature change (Section 7.5.2), longer averaging periods are useful. The change in ERF from the second half of the 19th century (1850–1900) compared with a recent period (2006–2019) is 2.20 [1.53 to 2.91] W m^{-2}, of which 1.71 [1.51 to 1.92] W m^{-2} is due to CO_2.

7.3.5.3 Temperature Contribution of forcing agents

The estimated contribution of forcing agents to the 2019 global surface air temperature (GSAT) change relative to 1750 is shown in Figure 7.7. These estimates were produced using concentration-derived ERF timeseries presented in Chapter 2, Figure 2.10 and described in Supplementary Material 7.SM.1.3. The resulting GSAT changes over time are shown in Figure 7.8. The historical timeseries of ERFs for the WMGHGs can be derived by applying the ERF calculations of Section 7.3.2 to the observed timeseries of WMGHG concentrations in Chapter 2, Section 2.2.

These ERF timeseries are combined with a two-layer emulator (Cross-Chapter Box 7.1, Supplementary Material 7.SM.2) using a 2,237-member constrained Monte Carlo sample of both forcing uncertainty (by sampling ERF ranges) and climate response (by sampling ECS, TCR and ocean heat capacity ranges). The net model warming over the historical period is matched to the assessment of historical GSAT warming from 1850–1900 to 1995–2014 of 0.85 [0.67 to 0.98]°C (Chapter 2, Cross-Chapter Box 2.3) and ocean heat content change from 1971 to 2018 (Section 7.2.2.2), therefore the model gives the breakdown of the GSAT trend associated with different forcing mechanisms that are consistent with the overall GSAT change. The model assumes that there is no variation in feedback parameter across forcing mechanism (see Section 7.3.1) and variations in the effective feedback parameter over the historical record (Section 7.4.4). The distribution of ECS was informed by Section 7.5.5 and chosen to approximately maintain the best estimate and *likely/very likely* ranges assessed in that section (see also Supplementary Material 7.SM.2). The TCR has an ensemble median value of 1.81°C, in good agreement with Section 7.5.5. Two error bars are shown in Figure 7.7. The dashed error bar shows the contribution of ERF uncertainty (as assessed in the Section 7.3 subsections) employing the best estimate of climate response with an ECS of 3.0 °C. The solid bar is the total response uncertainty using the Section 7.5.5 assessment of ECS. The uncertainty in the historic temperature contributions for the different forcing agents are mostly due to uncertainties in ERF, yet for the WMGHG the uncertainty is dominated by the climate response as its ERF is relatively well known (Figure 7.7). From the assessment of emulator responses in Cross-Chapter Box 7.1, there is *high confidence* that calibrated emulators such as the one employed here can represent the historical GSAT change from 1850-1900 to 1995–2014 to within 5% for the best estimate and 10% for the *very likely* range (Supplementary Table 7.SM.4). This gives *high confidence* in the overall assessment of GSAT change for the response to ERFs over 1750–2019 derived from the emulator.

The total human forced GSAT change from 1750–2019 is calculated to be 1.29 [1.00 to 1.65] °C (*high confidence*). Although the total emulated GSAT change has *high confidence*, the confidence of the individual contributions matches those given for the ERF assessment in Section 7.3 subsections. The calculated GSAT change is comprised of a well-mixed greenhouse gas warming of 1.58 [1.17 to 2.17] °C (*high confidence*), a warming from ozone changes of 0.23 [0.11 to 0.39] °C (*high confidence*), a cooling of –0.50 [–0.22 to –0.96] °C from aerosol effects (*medium confidence*). The aerosol cooling has considerable regional time dependence (Chapter 6, Section 6.4.3) but has weakened slightly over the last 20 years in the global mean (Figure 7.8 and Chapter 2, Figure 2.10). There is also a –0.06 [–0.15 to +0.01] °C contribution from surface reflectance changes which dominated by land-use change (*medium confidence*). Changes in solar and volcanic activity are assessed to have together contributed a small change of –0.02 [–0.06 to +0.02] °C since

ACCEPTED VERSION SUBJECT TO FINAL EDITING

1750 (*medium confidence*).

The total (anthropogenic plus natural) emulated GSAT between 1850–1900 and 2010–2019 is 1.14 [0.89 to 1.45]°C, compared to the assessed GSAT of 1.06 [0.88 to 1.21] °C (Section 2.3.1; Cross Chapter Box 2.3). The emulated response is slightly warmer than the observations and has a larger uncertainty range. As the emulated response attempts to constrain to multiple lines of evidence (Supplementary Material 7.SM.2), only one of which is GSAT, they should not necessarily be expected to exactly agree. The larger uncertainty range in the emulated GSAT compared to the observations is reflective of the uncertainties in ECS, TCR and ERF (particularly the aerosol ERF) which drive the emulator response.

The emulator gives a range of GSAT response for the 1750 to the 1850–1900 period of 0.09 [0.04 to 0.14] °C from a anthropogenic ERFs. These results are used as a line of evidence for the assessment of this change in Chapter 1 (Cross-Chapter Box 1.2), which gives an overall assessment of 0.1 °C [*likely* range -0.1 to 0.3] °C.

[START FIGURE 7.7 HERE]

Figure 7.7: The contribution of forcing agents to 2019 temperature change relative to 1750 produced using the two-layer emulator (Supplementary Material 7.SM.2), constrained to assessed ranges for key climate metrics described in Cross-Chapter Box 7.1. The results are from a 2,237-member ensemble. Temperature contributions are expressed for carbon dioxide, other well-mixed greenhouse gases (WMGHGs), ozone, stratospheric water vapour, surface albedo, contrails and aviation-induced cirrus, aerosols, solar, volcanic, and total. Solid bars represent best estimates, and *very likely* (5–95%) ranges are given by error bars. Dashed error bars show the contribution of forcing uncertainty alone, using best estimates of ECS (3.0°C), TCR (1.8°C) and two-layer model parameters representing the CMIP6 multi-model mean. Solid error bars show the combined effects of forcing and climate response uncertainty using the distribution of ECS and TCR from Tables 7.13 and 7.14, and the distribution of calibrated model parameters from 44 CMIP6 models. Non-CO_2 WMGHGs are further broken down into contributions from methane (CH_4), nitrous oxide (N_2O) and halogenated compounds. Surface albedo is broken down into land use changes and light absorbing particles on snow and ice. Aerosols are broken down into contributions from aerosol-cloud interactions (ERFaci) and aerosol-radiation interactions (ERFari). Further details on data sources and processing are available in the chapter data table (Table 7.SM.14).

[END FIGURE 7.7 HERE]

Figure 7.8 presents the GSAT timeseries using ERF timeseries for individual forcing agents rather than their aggregation. It shows that for most of the historical period the long timescale total GSAT trend estimate from the emulator closely follows the CO_2 contribution. The GSAT estimate from non-CO_2 greenhouse gas forcing (from other WMGHGs and ozone) has been approximately cancelled out in the global average by a cooling GSAT trend from aerosol. However, since 1980 the aerosol cooling trend has stabilised and may have started to reverse so over the last few decades the long-term warming has been occurring at a faster rate than that expected by CO_2 alone (*high confidence,* see also Chapter 2, Section 2.2.6 and 2.2.8). Throughout the record, but especially prior to 1930, periods of volcanic cooling dominate decadal variability. These estimates of the forced response are compared with model simulations and attributable warming estimates in Chapter 3, Section 3.3.1.

[START FIGURE 7.8 HERE]

Figure 7.8: Attributed global surface air temperature change (GSAT) from 1750 to 2019 produced using the two-layer emulator (Supplementary Material 7.SM.2), forced with ERF derived in this chapter (displayed in Chapter 2, Figure 2.10) and climate response constrained to assessed ranges for key climate metrics described in Cross-Chapter Box 7.1. The results shown are the medians from a 2,237-member ensemble that encompasses uncertainty in forcing and climate response (year-2019 best

ACCEPTED VERSION SUBJECT TO FINAL EDITING

estimates and uncertainties are shown in Figure 7.7 for several components). Temperature contributions are expressed for carbon dioxide, methane, nitrous oxide, other well-mixed greenhouse gases (WMGHGs), ozone, aerosols, other anthropogenic forcings, total anthropogenic, solar, volcanic, and total. Shaded uncertainty bands show *very likely* ranges. Further details on data sources and processing are available in the chapter data table (Table 7.SM.14).

[END FIGURE 7.8 HERE]

[START CROSS-CHAPTER BOX 7.1 HERE]

Cross-Chapter Box 7.1: Physical emulation of Earth System Models for scenario classification and knowledge integration in AR6

Contributors: Zebedee Nicholls (Australia), Malte Meinshausen (Australia/Germany), Piers Forster (UK), Kyle Armour (USA), Terje Berntsen (Norway), William Collins (UK), Christopher Jones (UK), Jared Lewis (Australia/New Zealand), Jochem Marotzke (Germany), Sebastian Milinski (Germany), Joeri Rogelj (Austria/Belgium), Chris Smith (UK)

Climate model emulators are simple physically-based models that are used to approximate large-scale climate responses of complex Earth System Models (ESMs). Due to their low computational cost they can populate or span wide uncertainty ranges that ESMs cannot. They need to be calibrated to do this and, once calibrated, they can aid inter-ESM comparisons and act as ESM extrapolation tools to reflect and combine knowledge from ESMs and many other lines of evidence (Geoffroy et al., 2013a; Good et al., 2013; Smith et al., 2018a). In AR6, the term 'climate model emulator' (or simply emulator) is preferred over 'simple' or 'reduced-complexity climate model' to reinforce their use as specifically calibrated tools (Cross-Chapter Box 7.1, Figure 1). Nonetheless, simple physically-based climate models have a long history of use in previous IPCC reports (Chapter 1, Section 1.5.3.4). Climate model emulators can include carbon and other gas cycles and can combine uncertainties along the cause-effect chain from emissions to temperature response. AR5(Collins et al., 2013a) used the MAGICC6 emulator (Meinshausen et al., 2011a) in a probabilistic setup (Meinshausen et al., 2009) to explore the uncertainty in future projections. A simple impulse response emulator (Good et al., 2011) was also used to ensure a consistent set of ESM projections could be shown across a range of scenarios. AR5 WGI Chapter 8 (Myhre et al., 2013b) employed a two-layer emulator for quantifying Global Temperature Potentials (GTP). In AR5 WGIII (Clarke et al., 2014), MAGICC6 was also used for the classification of scenarios, and in AR5 Synthesis Report (IPCC, 2014) this information was used to estimate carbon budgets. In SR1.5, two emulators were used to provide temperature projections of scenarios: the MAGICC6 model, which was used for the scenario classification, and the FaIR1.3 model (Millar et al., 2017; Smith et al., 2018a).

SR1.5 found that the physically-based emulators produced different projected non-CO_2 forcing and identified the largely unexplained differences between the two emulators used as a key knowledge gap (Forster et al., 2018). This led to a renewed effort to test the skill of various emulators. The Reduced Complexity Model Intercomparison Project (RCMIP; Nicholls et al. (2020)) found that the latest generation of the emulators can reproduce key characteristics of the observed changes in global surface air temperature (GSAT) together with other key responses of ESMs (Cross-Chapter Box 7.1, Figure 1a). In particular, despite their reduced structural complexity, some emulators are able to replicate the non-linear aspects of ESM GSAT response over a range of scenarios. GSAT emulation has been more thoroughly explored in the literature than other types of emulation. Structural differences between emulation approaches lead to different outcomes and there are problems with emulating particular ESMs. In conclusion, there is *medium confidence* that emulators calibrated to single ESM runs can reproduce ESM projections of the forced GSAT response to other similar emissions scenarios to within natural variability (Meinshausen et al., 2011b; Geoffroy et al., 2013a; Dorheim et al., 2020; Nicholls et al., 2020; Tsutsui, 2020), although larger differences can remain for scenarios with very different forcing characteristics. For variables other than GSAT there has not yet been a comprehensive effort to evaluate the performance of emulators.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Application of emulators in AR6 WGI

Cross-Chapter Box 7.1 Table 1 shows the use of emulators within the WGI Report. The main use of emulation in the Report is to estimate GSAT change from Effective Radiative Forcing (ERF) or concentration changes, where various versions of a two layer energy budget emulator are used. The two-layer emulator is equivalent to a two-timescale impulse response model (Geoffroy et al., 2013b, Supplementary Material 7.SM.2). Both a single configuration version and probabilistic forms are used. The emulator is an extension of the energy budget equation (Equation 7.1) and allows for heat exchange between the upper- and deeper-ocean layers, mimicking the ocean heat uptake that reduces the rate of surface warming under radiative forcing (Gregory, 2000; Held et al., 2010; Winton et al., 2010; Armour, 2017; Mauritsen and Pincus, 2017; Rohrschneider et al., 2019). Although the same energy budget emulator approach is used, different calibrations are employed in various sections, to serve different purposes and keep lines of evidence as independent as possible. Chapter 9 additionally employs projections of ocean heat content from the Chapter 7 two-layer emulator to estimate the thermostatic component to future sea-level rise (see Chapter 9, Section 9.6.3 and Supplementary Material 7.SM.2).

Emission-driven emulators, as opposed to ERF- or concentration-driven emulators are also used in the Report. In Chapter 4 (Section 4.6) MAGICC7 is used to emulate GSAT beyond 2100 since its long-term response has been assessed to be fit-for-purpose to represent the behaviour of ESMs. In Chapter 5 (Section 5.5) MAGICC7 is used to explore the non-CO_2 GSAT contribution in emissions scenarios. In Chapter 6 and Chapter 7 (Section 7.6), two-layer model configurations were tuned to match the probabilistic GSAT responses of FaIRv1.6.2 and MAGICC7 emission-driven emulators. For Chapter 6 the two median values from FaIRv1.6.2 and MAGICC7 emulators are averaged and then matched to the best-estimate ECS of 3°C and TCR of 1.8 °C (Table 7.13 and Table 7.14) under the best-estimate ERF due to a doubling of CO_2 of 3.93 W m^{-2} (Table 7.4). For Section 7.6 a distribution of responses are used from the two emulators to estimate uncertainties in Global Temperature-change Potentials.

Emission-driven emulators for scenario classification in AR6 WGIII

As in AR5 and SR1.5, emission-driven emulators are used to communicate outcomes of the physical climate science assessment and uncertainties to quantify the temperature outcome associated with different emission scenarios. In particular, the computational efficiency of these emulators allows the analysis of a large number of multi-gas emissions scenarios in terms of multiple characteristics, e.g., year of peak temperature or the 2030 emission levels in line with keeping global warming to below 1.5°C or 2.0 ºC.

Four emission-driven emulators have been considered as tools for WGIII to explore the range of GSAT response to multiple scenarios beyond those assessed in WGI. The four emulators are CICERO-SCM (Skeie et al., 2017, 2021), FaIRv1.6.2 (Millar et al., 2017; Smith et al., 2018a), MAGICC7 (Meinshausen et al., 2009) and OSCARv3.1.1 (Gasser et al., 2017a, 2020). Each emulator's probabilistic distribution has been calibrated to capture the relationship between emissions and GSAT change. The calibration is informed by the WGI assessed ranges of ECS, TCR, historical GSAT change, ERF, carbon cycle metrics and future warming projections under the (concentration-driven) SSP scenarios. The emulators are then provided as a tool for WGIII to perform a GSAT-based classification of mitigation scenarios consistent with the physical understanding assessed in WGI.. The calibration step reduced the emulator differences identified in SR1.5. Note that evaluation of both central and range estimates of each emulator's probabilistic projections is important to assess the fitness-for-purpose for the classification of scenarios in WGIII based on information beyond the central estimate of GSAT warming.

[START CROSS-CHAPTER BOX 7.1, FIGURE 1 HERE]

Cross-Chapter Box 7.1, Figure 1: A comparison between the global-mean surface air temperature response of various calibrated simple climate models, assessed ranges and Earth System Models. The top panels compare the assessed historical GSAT time series (Chapter 2, Cross Chapter Box 2.3) with four multi-gas emulators calibrated to replicate numerous assessed ranges (Cross-Chapter Box 7.1, Table 2 below) (panel a) and also compares idealized CO_2-only concentration scenario response for one ESM (IPSL CM6A-LR) and multiple emulators which participated in RCMIP Phase 1 (Nicholls et al., 2020) calibrated to that single ESM (panel b). The bottom panels compare this Report's assessed ranges for GSAT warming (Chapter 4, Box 4.1) under the multi-gas scenario SSP1-2.6 with the same calibrated emulators as in panel a (panel c and d). For context, a range of CMIP6 ESM results are also shown (thin lines in bottom-left panel c and open circles in bottom-right panel d). Panel b) adapted from Nicholls et al. (2020). Further details on data sources and processing are available in the chapter data table (Table 7.SM.14).

[END CROSS-CHAPTER BOX 7.1, FIGURE 1 HERE]

MAGICC7 and FaIRv1.6.2 emission based emulators are able to represent the WGI assessment to within small differences (defined here as within typical rounding precisions of ±5% for central estimates and ±10% for ranges) across more than 80% of metric ranges (Cross-Chapter Box 7.1, Table 2 below). Both calibrated emulators are consistent with assessed ranges of ECS, historical GSAT, historical ocean heat uptake, total greenhouse gas ERF, methane ERF and the majority of the assessed SSP warming ranges. FaIRv1.6.2 also matches the assessed central value of TCRE and airborne fraction. Whereas, MAGICC7 matches the assessed TCR ranges as well as providing a closer fit to the SSP warming ranges for the lower emission scenarios. In the evaluation framework considered here, CICERO-SCM represents historical warming to

ACCEPTED VERSION SUBJECT TO FINAL EDITING

within 2% of the assessed ranges and also represents future temperatures ranges across the majority of the assessment although it lacks the representation of the carbon cycle. In this framework, OSCARv3.1.1 is less able to represent the assessed projected GSAT ranges although it matches the range of airborne fraction estimates closely and the assessed historical GSAT *likely* range to within 0.5%. Despite these identified limitations, both CICERO-SCM and OSCARv3.1.1 provide additional information for evaluating the sensitivity of scenario classification to model choice.

How emulators match the assessed ranges used for the evaluation framework is summarised here and in Table 2. The first is too low projections in 2081–2100 under SSP1-1.9 (8% or 15% too low for the central estimate and 15% or 25% too low for the lower end in the case of MAGICC7 or FaIRv1.6.2, respectively). The second is the representation of the aerosol effective radiative forcing (both MAGICC7 and FaIRv1.6.2 are greater than 8% less negative than the central assessed range and greater than 10% less negative for the lower assessed range), as energy balance models struggle to reproduce an aerosol ERF with a magnitude as strong as the assessed best estimate and still match historical warming estimates. Both emulators have medium to large differences compared to the TCRE and airborne fraction ranges (see note of Table 2). Finally, there is also a slight overestimate of the low-end of the assessed historical GSAT range.

Overall, there is *high confidence* that emulated historical and future ranges of GSAT change can be calibrated to be internally-consistent with the assessment of key physical-climate indicators in this Report: greenhouse gas ERFs, ECS and TCR. When calibrated to match the assessed ranges of GSAT and multiple physical climate indicators, physically-based emulators can reproduce the best estimate of GSAT change over 1850–1900 to 1995–2014 to within 5% and *very likely* range of this GSAT change to within 10%. MAGICC7 and FaIRv1.6.2 match at least two-thirds of the Chapter 4 assessed projected GSAT changes to within these levels of precision.

Notes. Metrics calibrated against are equilibrium climate sensitivity, ECS (Section 7.5); transient climate response to cumulative emissions of carbon dioxide, TCRE (Chapter 5, Section 5.5); transient climate response, TCR (Section 7.5), historical GSAT change (Chapter 2, Section 2.3), ocean heat uptake (Section 7.2 and Chapter 2, Section 2.3) and effective radiative forcing, ERF (Section 7.3), carbon cycle metrics, namely airborne fractions of idealized CO_2 scenarios (taking the *likely* range as twice the standard deviation across the models analysed in Arora et al. (2020), see also Chapter 5, Table 5.7, cross-AR6 lines of evidence row) and GSAT projections under the concentration-driven SSP scenarios for the near-term (2021–2040), mid-term (2041–2060) and long-term (2081–2100) relative to 1995–2014 (Chapter 4, Table 4.2). See Supplementary Table 7.SM.4 for a version of this table with the absolute values rather than percentage differences. The columns labelled "upper" and "lower" indicate 5% to 95% ranges, except for the variables demarcated with an asterisk or double asterisk (* or **), where they denote *likely* ranges from 17% to 83%. Note that the TCRE assessed range (**) is wider than the combination of the TCR and airborne fraction to account for uncertainties related to model limitations (Chapter 5, Table 5.7) hence it is expected that the emulators are too narrow on this. particular metric and/or too wide on TCR and airborne fraction. For illustrative purposes, the cells are coloured as follows: white cells indicate small differences (up to ±5% for the central value and +10% for the ranges), light blue and light teal cells indicate medium differences (up to +10% and -10% for light blue and light teal for central values, respectively; up to ±20% for the ranges) and darker cells indicate larger positive (blue) or negative (teal) differences

ACCEPTED VERSION SUBJECT TO FINAL EDITING

(note that values are rounded after the colours are applied).

[END CROSS-CHAPTER BOX 7.1 HERE]

7.4 Climate feedbacks

The magnitude of global surface temperature change primarily depends on the strength of the radiative forcings and feedbacks, the latter defined as the changes of the net energy budget at the top of atmosphere (TOA) in response to a change in the GSAT (Box 7.1, Equation 7.1). Feedbacks in the Earth system are numerous, and it can be helpful to categorise them into three groups: (1) physical feedbacks; (2) biogeophysical and biogeochemical feedbacks; and (3) long-term feedbacks associated with ice sheets. The physical feedbacks (for example, associated with changes in lapse-rate, water vapour, surface albedo, or clouds; Sections 7.4.2.1-7.4.2.4) and biogeophysical/biogeochemical feedbacks (for example, associated with changes in methane, aerosols, ozone, or vegetation; Section 7.4.2.5) act both on time scales that are used to estimate the equilibrium climate sensitivity (ECS) in models (typically 150 years, see Box 7.1) and on longer time scales required to reach equilibrium. Long-term feedbacks associated with ice sheets (Section 7.4.2.6) are relevant primarily after several centuries or more. The feedbacks associated with biogeophysical/biogeochemical processes and ice sheets, often collectively referred to as Earth system feedbacks, had not been included in conventional estimates of the climate feedback (e.g., Hansen et al., 1984), but the former can now be quantified and included in the assessment of the total (net) climate feedback. Feedback analysis represents a formal framework for the quantification of the coupled interactions occurring within a complex Earth system in which everything influences everything else (e.g., Roe, 2009). As used here and presented in Section 7.4.1, its primary objective is to identify and understand the key processes that determine the magnitude of the surface temperature response to an external forcing. For each feedback, the basic underlying mechanisms and their assessment are presented in Section 7.4.2.

Up until AR5, process understanding and quantification of feedback mechanisms were based primarily on global climate models. Since AR5, the scientific community has undertaken a wealth of different alternative approaches, including observational and fine-scale modelling approaches. This has in some cases led to more constrained feedbacks and, on the other hand, uncovered shortcomings in global climate models, which are starting to be corrected. Consequently, AR6 achieves a more robust assessment of feedbacks in the climate system that is less reliant on global climate models than in earlier assessment reports.

It has long been recognized that the magnitude of climate feedbacks can change as the climate state evolves over time (Manabe and Bryan, 1985; Murphy, 1995), but the implications for projected future warming have been investigated only recently. Since AR5, progress has been made in understanding the key mechanisms behind this time- and state-dependence. Specifically, the state-dependence is assessed by comparing climate feedbacks between warmer and colder climate states inferred from paleoclimate proxies and model simulations (Section 7.4.3). The time-dependence of the feedbacks is evident between the historical period and future projections and is assessed to arise from the evolution of the surface warming pattern related to changes in zonal and meridional temperature gradients (Section 7.4.4).

7.4.1 Methodology of the feedback assessment
